Several classes of innate host proteins function in antiviral defense. These include natural antibodies, which may play a role in defense against some viral infections, as well as pentraxins and complement proteins.[10] Some viruses may be directly inactivated by complement activation or be destroyed by phagocytic cells that bind and ingest complement-bound virions. Several proinflammatory cytokines and chemokines induced by virus infection also play key roles in defense. Foremost among these is IL-1 and other members of the IL-1 family, including IL-18 and IL-33.[11] These cytokines influence both innate and adaptive immune cells and play critical roles in antiviral defense. Other antiviral cytokines are produced early following infection, such as TNF-α, IFN-γ, IL-12, IL-6, and chemokines, such as MIP-1α. In particular, IL-12 is a potent inducer of IFN-γ from NK cells. Inflammatory chemokines may also play an important role in innate antiviral defense by orchestrating macrophage, neutrophil, DC, and NK cell responses at the site of infection. Not only are these components of innate immunity involved in mediating initial protection against viruses; several components (*e.g.,* the PRRs; the cytokines IFN-I, IL-I, IL-33, and IL-12; and phagocytes, including macrophages, monocytes, and DCs) serve to shape the nature and effectiveness of the subsequent adaptive response to viral pathogens. For instance, DCs require innate signals, such as IFN-I and IL-12, for maturation and optimal T-cell activation. Furthermore, CD8$^+$ T cells responding to viruses need IFN-I and IL-33 signals for expansion and memory formation. Thus both the magnitude and the type of innate response induced by virus infection have a marked influence on the generation of adaptive immune responses.

ADAPTIVE IMMUNITY TO VIRUSES

Innate immunity generally only slows, rather than stops, viral infection, allowing time for the adaptive immune response to begin. The two major divisions of adaptive immunity, antibody-mediated and T-cell–mediated, are mainly directed at different targets. Antibodies usually function by binding to free viral particles and, in so doing, block infection of the host cell (Chapter 15). In contrast, T cells act principally by recognizing and destroying virus-infected cells or by orchestrating an inflammatory response that includes several antiviral components (Chapters 16, 17). As all viruses replicate within cells and many can spread directly between cells without reentering the extracellular environment, resolution of infection is reliant more on T-cell function than on antibody function. However, broadly neutralizing antiviral antibodies have the potential to be effective therapies against many different human infections, including HIV, influenza viruses, and Ebola virus. Recent advances have allowed researchers to isolate and identify human monoclonal antibodies (mAbs) against these and other pathogens,[12] offering promise of new therapies as well as significant insight for vaccine design. Antiviral antibodies are also very important as an immunoprotective barrier against reinfection. It is the presence of antibodies at portals of entry—most often mucosal surfaces—that is of particular relevance to influenza, HSV, and HIV infections.[13] Yet, how to generate vaccines that induce optimal antibody responses, including broadly neutralizing antibodies, remains an important unsolved problem.

Initiation of adaptive immunity is closely dependent on early innate mechanisms that activate antigen-presenting cells (APCs), principally subsets of DCs. APCs and lymphocytes are drawn into lymphoid tissues by chemokine and cytokine signals and are retained there for a few days to facilitate effective intercellular interactions. The architecture of the secondary lymphoid tissues supports the coordinated interactions among the cells of the adaptive immune system[14] through a network of supportive stromal cells and local chemokine gradients[15](Chapter 2). The induction events occur in lymph nodes draining an infection site or in the spleen if virus enters the bloodstream. The passage of viral antigens to lymph nodes usually occurs in DCs. Some viruses are able to compromise the function of APCs, such as HSV and measles virus, which can inhibit DC maturation.

B-cell activation occurs following antigen encounter in the B-cell follicles, and possibly the T-cell zones, in the spleen or lymph nodes. Some activated B cells become short-lived plasma cells, whereas others move to the edges of the B-cell follicles and interact with antigen-specific helper CD4$^+$ T cells via presentation of antigenic peptides on B-cell MHC class II molecules. These Bcl6-dependent CD4 T follicular helper (Tfh) cells are specialized for providing help for B-cell responses and are needed to promote and regulate B-cell responses.[16] Activated B cells initiate germinal center (GC) reactions with the help of CD4 Tfh cells, ensuring somatic hypermutation and affinity maturation for the selection of high-affinity, antibody-producing, long-lived plasma cells, as well as memory B cells.[17] At the molecular level, upregulation of the transcription factors Blimp-1, XBP-1, and IRF-4 dictates plasma cell formation, whereas Pax-5 expression delineates B cells destined for GC reactions and the memory B-cell lineage.

Antibody binding to epitopes expressed by native proteins at the surface of free virions usually blocks viral attachment or penetration of target cells. Sometimes the consequence is viral lysis (with complement proteins also involved), opsonization, or sensitization for destruction by Fc receptor–bearing cells that mediate antibody-dependent cellular cytotoxicity (ADCC). Occasionally, however, Fc receptor binding of antibody-bound virus may facilitate infection and result in more severe tissue damage. This occurs in Dengue fever and may happen in some instances in HIV infection. The antibody involved in the protection of mucosal surfaces in humans is predominantly secretory immunoglobulin A (IgA), but serum-derived IgG may also be protective, particularly in such sites as the vaginal mucosa.[13] Both antibody isotypes act mainly to block infection of epithelial cells, although in some instances, the antibody may transport antigen from within the body across epithelial cells to the outside. Mucosal antibody persists for a much shorter period compared with serum antibody, which explains, in part, why immunity to mucosal pathogens is usually of much shorter duration compared with immunity to systemic viral infections.

KEY CONCEPTS

Antiviral T- and B-Cell Immunity

Effector Systems	Recognized Molecules	Control Mechanisms
Antibody	Surface proteins or virions	Neutralization of virus, opsonization, or destruction of infected cells by ADCC
Antibody + complement	Surface proteins expressed on infected cells	Infected cell destruction by ADCC or complement-mediated lysis
Mucosal antibody (IgA)	Surface proteins or virions	Viral neutralization, opsonization, and transcytosis
$CD4^+$ T cells	Viral peptides (10–20 mers) presented on MHC class II surface, internal or nonstructural proteins presented by APCs	Antiviral cytokine and chemokine production; help for $CD8^+$ T-cell and B-cell responses; killing infected cells; regulatory functions to reduce immunopathology
$CD8^+$ T cells	Viral peptides (8–10 mers) presented on MHC class I surface, internal, or nonstructural proteins presented on infected cells or by cross-presentation	Killing infected cells or purging virus without cell death; antiviral cytokine and chemokine production

ADCC, antibody-dependent cellular cytotoxicity; APC, antigen-presenting cell; IgA, immunoglobulin A; MHC, major histocompatibility complex.

FIG 25.2 Expansion/Contraction/Memory Phases of Adaptive Immunity and Memory Cell Subsets. (A) Dynamics of primary and secondary (recall) T-cell responses to viral infection. Both primary and recall T-cell responses undergo expansion and contraction phases, followed by stable immune memory. Recall responses induce a larger effector pool and reduced contraction further boosting the memory pool. (B) Effector and memory T-cell differentiation. Antigen stimulation expands effector cells, most of which die during the contraction phase. Effector memory T (T_{EM}) cells that are formed gradually convert to central memory T (T_{CM}) cells over time, with corresponding changes in surface marker expression. Some effector T cells develop into resident memory T (T_{RM}) cells that persist in the tissues and do not reenter the circulation.

Like B-cell responses, T-cell responses to viral infections also begin within lymphoid tissues. Specific $CD8^+$ CTL precursors recognize antigen in the context of MHC class I–peptide antigen complexes on DCs. The $CD8^+$ T cells become activated, proliferate, and differentiate into effectors. Expansion of these naïve antigen-specific precursors is considerable, often exceeding 10 000-fold, and results in an effector population that can account for 40% or more of a host's total $CD8^+$ T-cell population (Fig. 25.2). Various factors, including antigen and APCs, costimulatory molecules (*e.g.*, CD28 and 4–1BB), and inflammatory cytokines (*e.g.*, IFN-I and IL-12) are required to program the development of functional effector lymphocytes. In some infections, $CD4^+$ T-cell help is also important to prime robust CTL responses via signals, including CD40 that are delivered to DCs.[18] Activated CTL effectors then exit lymphoid organs and access almost all body locations via the bloodstream. However, effectors do not stay activated for long once the virus is cleared, and approximately 95% die by a process termed *activation-induced cell death.*

Following this contraction phase, the remaining cells differentiate into memory cells, which remain as a more or less stable population in the host for many years. They represent an expanded pool of CTL precursors that can be activated upon secondary encounter with antigen and provide enhanced protection upon reinfection with the same virus (see next section). Although much of our knowledge of T-cell responses to viruses has been obtained from murine studies, it is increasingly clear that the fundamental principles are the same or similar in humans.[19]

T-cell immunity against a particular virus involves both CD4$^+$ and CD8$^+$ T-cell subsets that recognize peptides derived from viral antigens bound to surface MHC proteins (class II and class I, respectively) (Chapters 5, 6). Complexes of viral peptides bound to MHC class II proteins are generated by APCs from scavenged and processed virus-infected cells or viral particles. Antigen–MHC class I complexes are expressed on the surface of infected cells, and antigen can also be transferred to APCs from infected cells by a process known as *cross-presentation.* Recent experiments in mice have also demonstrated a role for transfer of antigen between DCs as they migrate from infected tissues to the lymphoid tissues. Multiple subsets of DCs exist and specialize somewhat in antigen presentation on MHC-I or MHC-II.[20] During the process of activation, T cells can receive signals from multiple DC types in a temporally controlled sequence that coordinates CD4$^+$ and CD8$^+$ T-cell interactions.[18] Use of MHC class I and class II tetramers to directly visualize antigen-specific CD8$^+$ and CD4$^+$ T-cell responses, respectively, has demonstrated the significant size of T-cell responses to viruses, such that the majority of the activated T cells seen at the peak of the response are virus-specific.

CTLs function by recognizing virus-infected cells and killing them; this often involves perforins and cytotoxic granules containing granzymes. Effector CTLs can also induce death in target cells following engagement of the Fas ligand on the CTL with Fas on target cells. Both pathways lead to apoptosis of the target cell, involving the degradation of nucleic acids, including those of the virus. Alternatively, CD8$^+$ T cells also mediate defense through the release of various cytokines after antigen recognition. Some of the cytokines and chemokines most highly produced by CTLs include IFN-γ, TNF-α, lymphotoxin-α, and RANTES (CCL5) (Chapters 9, 10). These cytokines can have multiple antiviral effects on infected cells and on the cells around them, including purging of virus from infected cells without killing the cells. This is particularly important for such viruses as HSV, which infects nonrejuvenating cells, such as nerve cells.

CD4$^+$ T cells are involved in antiviral defense as well as being modulators of inflammatory reactions to viruses. Multiple functional subsets of CD4$^+$ T cells are recognized based largely on the types of cytokines produced when they recognize antigen. CD4$^+$ T cells are more broadly reactive than CD8$^+$ T cells; they recognize larger peptides processed from viral proteins and are restricted by MHC class II. These CD4$^+$ T cells participate in antiviral immunity in several ways. They can act as helper cells for the development of high-affinity antibody responses and for more functional CD8$^+$ T-cell responses.[16,21] Additionally, CD4$^+$ T cells act as effectors and orchestrate inflammatory reactions, which either serve a protective function or, in some cases, become prolonged causing chronic tissue damage (Chapter 16). The latter can happen in HCV-mediated hepatitis and HSV-mediated stromal keratitis. Occasionally, CD4$^+$ T cells can mediate direct cytotoxicity, but they are less effective than CD8$^+$ T cells. The principal subsets of CD4$^+$ T cells involved in inflammatory reactions are T helper-1 (Th1) cells (producing mainly IFN-γ, tumor necrosis factor [TNF]-α, IL-2) and Th17-producing cells (IL-17a and IL-22). A third effector subset, Th2 cells producing (IL-4, IL-5, and IL-13), also participates in inflammatory reactions, although in the case of viruses, these are usually more tissue damaging than protective. This situation can occur in responses to RSV infection. Regulatory T cells (Tregs) are a further subset of CD4$^+$ T cells of particular importance, since these cells largely act to regulate the function of effector subsets and, in so doing, influence the severity and duration of inflammatory reactions[22] (Chapter 18). Tregs produce antiinflammatory cytokines, such as IL-10 and TGF-β, and can be distinguished from other CD4$^+$ subsets by their expression of a unique transcription factor FoxP3. The balance of CD4$^+$ T-cell subset representation in response to a virus infection is critical. In situations where responses become overtly tissue damaging and chronic, the balance favors effector subsets. In such situations, changing the balance to favor Tregs can result in diminished lesions.

IMMUNOLOGICAL MEMORY

Immunological memory is a cardinal feature of adaptive immunity. The goal of vaccinology is to induce long-lived immunological memory to protect against reinfection (Chapter 90). Following infection with certain viruses, memory can be exceptionally long-lived, potentially for the life of the host (*e.g.,* yellow fever and smallpox viruses).[19,23] Memory is defined by the persistence of specific lymphocytes and antibody-producing plasma cells rather than that of antigen to induce continuous lymphocyte activation. Humoral memory to viruses involves long-lived plasma cells in bone marrow, which provide a continuous low-level source of serum antibody. This maintenance of humoral immunity also involves a population of homeostatically maintained memory B cells, which may be required to maintain stable numbers of long-lived plasma cells over time. The pool of memory T cells is regulated by low-level homeostatic division controlled by the cytokines IL-7 and IL-15. For memory CD8$^+$ T cells, IL-7 is primarily important for survival, whereas IL-15 is crucial for low-level proliferation to maintain the size of the memory T-cell pool.

KEY CONCEPTS

Principles of Antiviral Immunity

Many human viral infections are successfully controlled by the immune system.

Certain emerging viruses may overwhelm the immune system and cause severe morbidity and mortality.

Other viruses have developed mechanisms to overwhelm or evade the immune system and persist.

Individuals with defects in innate or adaptive immunity demonstrate more severe viral infections.

T-cell immunity is more important for control than are antibodies in many viral infections.

Antibodies are important to minimize reinfection, particularly at mucosal sites.

Immune memory is often sufficient to prevent secondary disease, although not in all viral infections.

Tissue-specific immune memory may be important to rapidly protect against reinfection at peripheral sites (*e.g.,* skin and mucosae).

Immunological memory is defined by a pool of antigen-specific cells whose increased frequency enables rapid control of viral reinfection (see Fig. 25.2). IL-7Rα-expressing effector T cells are the precursors of this memory pool. This population of cells, which constitutes about 5–10% of the effector pool, preferentially survives the contraction phase and gradually differentiates into a stable memory population.[24] Upon reinfection, these memory cells can be rapidly activated and, by virtue of their increased frequency, mediate more rapid clearance of the viral pathogen. Moreover, repeated stimulation of memory cells via multiple infections with the same virus, or prime-boost vaccine regimes, further increases the size of the antigen-specific memory T-cell pool.[25] Restimulation also affects the activation status and tissue distribution of memory T cells, which may enhance protection from viral infection in mucosal and other tissues.

Experiments in humans and mice have demonstrated that memory T cells are heterogeneous. Memory T cells were divided into effector memory (T_{EM}) and central memory (T_{CM}) subsets, defined by expression of two surface molecules involved in T-cell migration: CD62L and CCR7.[24] The $CD62L^{lo}CCR7^{lo}$ T_{EM} subset is found primarily in nonlymphoid tissues and the spleen, whereas the $CD62L^{hi}CCR7^{hi}$ T_{CM} subset is largely present in lymph nodes and the spleen. The current model predicts that effector T cells form the T_{EM} subset and that these cells gradually convert to a T_{CM} phenotype over time (Fig. 25.2B). Although the conditions that control the rate of this conversion are unknown, it is likely that the amounts of antigen and inflammatory signals received during the effector phase greatly influence this. It has also been shown that $CD4^+$ T-cell help is required for the generation of long-lived memory $CD8^+$ T cells, via interactions with DCs.[21]

Studies suggest that T_{CM} are capable of mounting stronger proliferative responses following reinfection. Tissue-specific homing of T_{EM} cells permits them to enter sites of potential viral infection, such as skin and mucosae. However, we now know that many memory T cells found at sites of previous viral infections take up long-term residence in tissues.[26] This includes skin, intestines, lungs, the liver, and the brain. These resident memory T cells (T_{RM} cells) are sequestered from the circulation and provide rapid protection against viruses, such as HSV, in skin, where they localize with a unique dendritic morphology and undergo slow surveillance of the tissue (Fig. 25.3). Notably, activation of T_{RM} cells can trigger enhanced early inflammation to drive local immunity. This is in contrast to T_{EM} cells, which continue to migrate through nonlymphoid tissues, rather than being sequestered in peripheral tissues, and also differs from the $CD8^+$ and $CD4^+$ T_{CM}, which migrate largely through lymphoid organs (spleen and lymph nodes). These differences may define the physiological *raison d'être* for these memory T-cell subsets, highlighting that measurement of memory T cells in human peripheral blood is a poor representation of the total-body memory T cell pool.

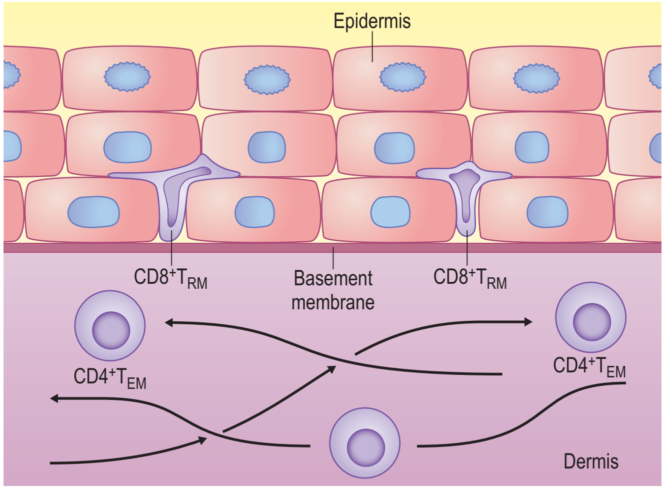

FIG 25.3 Unique Subsets of Memory $CD8^+$ and $CD4^+$ T Cells Reside Within Peripheral Tissues, at Sites of Previous Viral Infection, and Provide Rapid Protection Against Reinfection. Resident memory $CD8^+$ T cells (T_{RM}) remain localized in the epidermis in skin after herpes simplex virus (HSV) infection. Resident memory $CD4^+$ T (T_{EM}) cells continue to migrate through the dermal layers of skin, with access to blood and lymphoid tissues.

T_{RM} cells can be detected in tissues by using markers, such as CD69 and CD103, although these are imperfect identifiers, including in human tissues. T_{RM} cells in different anatomical locations share a common genetic signature and require common transcription factors for their formation. Yet, these cells also adopt unique gene expression that is imprinted by the tissue environment, and presumably imparts specialized functions on T_{RM} cells in each location. However, memory in certain peripheral tissues, such as lungs, appears to wane over time, suggesting that memory T cells may not persist in sufficient numbers in this site. This rationalizes a need for vaccines that induce optimal numbers of memory T cells in tissues as well as blood.

IMMUNE EVASION AND IMMUNITY TO CHRONIC VIRAL INFECTIONS

Many, if not all, viruses employ immune blunting or delay tactics to circumvent aspects of the immune system, allowing them time to replicate further or escape detection (Table 25.3).[27] One such mechanism may involve killing or infecting APCs. Viruses may also delay or prevent apoptosis induced by CTLs within infected cells. Other viral evasion measures aimed at the $CD8^+$ T cell–mediated antiviral defense system inhibit antigen processing, thereby minimizing effector CTL induction. To escape CTL killing, many viruses also downregulate the MHC molecules on the surface of infected cells. In addition, viruses may produce various mimics or modulators/inhibitors of cytokines, chemokines, or

TABLE 25.3 Mechanisms and Examples of Viral Immune Evasion

Mechanism	Example
Interference with viral antigen processing and presentation	HSV (ICP47), EBV (EBNA-1), HIV (Nef, Tat), HPV (E5), CMV (UL6)
Evasion of NK cell function	HIV (Nef), EBV (EBNA-1), CMV (UL40, UL18)
Inhibition of cell apoptosis	Adenovirus (RID complex and E1B), HIV (Nef), EBV (BHRF-1)
Destruction of T cells	HIV
Interference with antiviral cytokines and chemokines	EBV (IL-10 homologue), CMV(US28 chemokine receptor homologue), vaccinia virus (IL-18-binding protein), HIV (Tat chemokine activity)
Inhibition of complement action	HSV, pox viruses
Inhibition of DC maturation	HSV, vaccinia virus
Frequent antigenic variation	Influenza virus, HIV
Infection of immune privileged site	Measles virus, VZV and HSV (neurons)
Immune exhaustion	HIV, HCV, HBV

CMV, cytomegalovirus; DC, dendritic cell; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HIV, human immunodeficiency virus; HPV, human papillomavirus; HSV, herpes simplex virus; IL-18, interleukin-18; NK, natural killer; RID, receptor internalization and degradation; VZV, varicella-zoster virus.

other components of the immune system or their receptors. Viruses also resort to antigenic hypervariability to escape antibody or T-cell recognition. This can occur during transmission from host to host (*e.g.*, influenza virus), or within hosts during chronic infection through the generation of viral escape mutants. The latter is particularly important for HIV and HCV infections.

The success of many viral pathogens rests in their ability to subvert the host immune response. The most successful human viruses can escape the immune system and persist for the life of the host.[28] Two well-studied examples of this are CMV and EBV. T-cell responses to these viruses are prominent and readily detectable in humans, and yet the immune system is unable to clear either pathogen completely. However, these viruses generally remain undetectable in immunocompetent individuals. Other viral infections, such as those caused by the herpes viruses HSV and VZV, are marked by periods of latency when no virus can be detected. Yet, periods of viral reactivation, often triggered by stress, can lead to episodes of disease. These are controlled by the immune response, which plays a central role in controlling herpes virus latency.[29]

Many of the most medically important human viruses are associated with persistent viremia. These include those causing chronic infections, such as HIV, HCV, HBV, and human T-lymphotropic virus (HTLV), among others. Such chronic viral infections are marked by high levels of persisting antigen and can result in skewed T-cell immunodominance hierarchies, altered tissue localization of immune cells, and severely impaired T-cell function.[30] This altered T-cell function is hierarchical and results in functional T-cell defects ranging from reduced cytokine production and altered proliferative capacity (exhaustion) to death (deletion) of the responding T cells (Fig. 25.4).

Sustained viral antigen levels and inflammation are responsible for this immune dysfunction. This is in stark contrast to normal memory T-cell development, which occurs in the absence of persisting antigen (see previous section). Studies have demonstrated that signaling through multiple inhibitory receptors expressed on the cell surface contributes to exhaustion during chronic infections.[30] This includes the receptor programmed death (PD)-1, expression of which may be essential for preventing excessive immunopathology by effector T cells and yet appears to contribute directly to failed immunity to HIV infection and other chronic human viral infections. Although the molecular mechanisms of exhaustion remain unclear, differential involvement of transcription factors and altered gene expression define exhausted T cells. These studies implicated multiple inhibitory receptors as a potential therapeutic targets, and although combinations of these checkpoint inhibitor blockade therapies are proving highly beneficial to the treatment of certain cancers,[31] similarly efficacious responses have yet to be demonstrated during chronic virus infection.

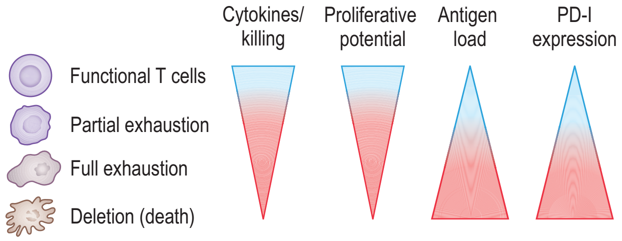

FIG 25.4 Hierarchical Model of T-Cell Exhaustion During Persistent Viral Infection. T-cell function (cytokine production, killing, and proliferative potential) is negatively influenced by increasing levels of antigen. Low levels of persistent antigen may lead to partial loss of function and intermediate levels of programmed death (PD)-1 expression. High, sustained levels of antigen over time can lead to full loss of function, high levels of PD-1, and eventually cell death (deletion).

OUTCOMES OF VIRUS INFECTION: IMMUNITY OR IMMUNOPATHOLOGY

Typically, individual humans respond to a virus infection in different ways. When the common cold or even pandemic influenza infection occurs, only a small percentage of exposed persons may develop overt clinical disease. In the prevaccine days, poliomyelitis was a much-feared consequence of poliovirus infection, but only a very small percentage of infected persons developed the paralyzing complications. Similarly, only an unfortunate few develop life-threatening meningoencephalitis following infection with the insect-transmitted West Nile virus. It is particularly characteristic of chronic viral infections that clinical expression is highly variable. With HCV, for example, in 70–80% of patients, some form of chronic liver disease develops, and the virus is not cleared. However, in up to 30%, the infection is controlled, the virus is cleared, and immunity to reinfection develops. The latter group of individuals make a type of immune response that includes protective antibodies along with an appropriate pattern of T-cell responsiveness.[32]

We do not fully understand the reasons for the varying outcomes of virus infections in different persons, and almost certainly multiple factors are involved. Many of these factors impact the response pattern made by the innate immune system, which, in turn, affects the magnitude and type of adaptive immune response that occurs. Some of the circumstances that do influence the outcome of infection include genetic susceptibility of the host, the age of the host when infected, the dose and route of infection, the variable induction in the host of antiinflammatory cells and proteins, and the presence of concurrent infections and past exposure to cross-reactive antigens.[32]

IMMUNOPATHOLOGY AND AUTOIMMUNITY

Immune responses against virus-infected cells often result in tissue damage, especially if cell killing is involved or if there is extensive recruitment and activation of inflammatory cell types, such as macrophages and sometimes neutrophils. If the response is brief and is quickly repaired, it is usually deemed an immunoprotective event. A prolonged tissue-damaging effect resulting from an immune reaction against viruses is considered immunopathology. Such situations most commonly involve persistent viruses, which are themselves often mildly cytodestructive in the absence of an immune reaction. Chronic tissue damage initiated by viruses can also result in development of an autoreactive and an occasionally oncogenic response. For example, some autoimmune diseases may be initiated or exacerbated by viral infections, but no named virus has been regularly incriminated as a cause of human autoimmune disease.[33] Circumstantial evidence exists for a virus link in multiple sclerosis (MS), insulin-dependent diabetes, and possibly systemic lupus erythematosus (SLE). In MS, many viruses have been isolated from patients, although no specific one has been tied to the disease etiology. The current hypothesis is that viral infections set up an

TABLE 25.4 Lesions Resulting From Immunopathology

inflammatory environment that may exacerbate or tip the balance toward disease in genetically susceptible individuals.

Immunopathological reactions involving viruses have several mechanisms, but T cells are usually involved as orchestrators of inflammatory events (Table 25.4). The clearest example of immunopathology involving a virus is lymphocytic choriomeningitis virus (LCMV) in the mouse. This model has dominated ideas and has set several paradigms in viral immunology in general. The first virus-induced immunopathological lesions recognized were glomerulonephritis and arteritis, noted in mice persistently infected with LCMV. The lesions were assumed to represent inflammatory reactions to tissue-entrapped immune complexes that activate complement. Similar immune complex–mediated lesions occur in other infections, including lung lesions found in severe influenza, respiratory syncytial virus infection, viral hepatitis, and arthritis. However, only rarely have viral antigens been shown to contribute to the antigen component of the complex. An example where the inclusion of viral antigen in immune complexes has been demonstrated is chronic HBV infection of humans. Autoimmune diseases, such as SLE, also result from immune complex–mediated tissue damage. However, evidence linking viruses to the etiology or pathogenesis of SLE is scarce, since the immune complexes in SLE do not appear to include viral antigens at any stage.

Thanks largely to the LCMV model, it is clear that $CD8^+$ T-cell recognition of viral antigens can result in tissue damage. In LCMV infection, damage occurs in the leptomeninges of immunocompetent mice infected intracerebrally. Hepatitis can also occur in mice infected intravenously. Neither lesion becomes evident if the $CD8^+$ T-cell response is suppressed. $CD8^+$ T cell–mediated immunopathology can be a causative mechanism of chronic hepatitis associated with HCV and HBV infection, although the tissue damage also involves inflammatory $CD4^+$ T cells. Additional viral immunopathology models where lesions result primarily from $CD8^+$ T-cell involvement include myocarditis and insulin-dependent diabetes associated with coxsackie B virus infection. In both instances, $CD8^+$ T cells mainly orchestrate events, but tissue damage may result from the bystander effects of cytokines and other molecules, such as lipid mediators, metalloproteinases, and components of the oxygen burst. Although coxsackie virus can be a cause of diabetes in the mouse, attempts to relate viral infection directly to the etiology of human diabetes have so far failed.

CLINICAL RELEVANCE

Hypothesized Role of Viruses in Autoimmunity

Molecular mimicry: similar epitopes shared by virus and host
Bystander activation: chronic release of cytokines and host antigens activates local autoreactive lymphocytes
Viral persistence: chronic viral antigen presentation on host cells leads to prolonged immunopathology

Immunopathological reactions against viruses can also involve subsets of $CD4^+$ T cells, which can be either Th1 or Th17 or both. One well-studied example involves persistent infection with Theiler virus in mice.[34] This infection causes a demyelinating syndrome that resembles the autoimmune disease experimental allergic encephalomyelitis. In both situations, $CD4^+$ T cells that produce Th1 cytokines appear to serve as pathological mediators. Furthermore, in both models an increase in the involvement of myelin-derived autoantigens occurs as the disease progresses. Once again, such observations indicate the possible role of a virus in an autoimmune disease. With the Theiler virus model, the virus persists in the nervous system and chronically stimulates $CD4^+$ T cells to secrete an array of cytokines. The demyelinating events appear to result from cytokine action on oligodendrocytes. Myelin components, such as myelin basic protein, proteolipid protein, and myelin oligodendroglial glycoprotein, may be released and can participate as additional antigen in immunoinflammatory events. This scenario is referred to as *epitope spreading.*

Another model of virus-induced immunopathology that mainly involves the Th1 subset of $CD4^+$ T cells is stromal keratitis caused by HSV infection (Fig. 25.5).[35] The pathogenesis of this immunopathological lesion is unusual in that it occurs and progresses when viral antigens can no longer be demonstrated. The chronic immunoinflammatory lesions are mainly orchestrated by $CD4^+$ T cells, but multiple early events induce the subsequent pathology. Viral replication, the production of certain cytokines and chemokines (IL-1, IL-6, IL-12, and CXCL8), recruitment of inflammatory cells (*e.g.,* neutrophils), and neovascularization of the avascular cornea all precede immunopathology. Recently, it has become evident that Th17 T cells participate in stromal keratitis lesions. The role of Th17 T cells as orchestrators of inflammatory reactions has been a major research focus, especially in lesions of autoimmune diseases.[36] When Th17 T cells are the principal mediators of tissue damage, abundant neutrophils are recruited to inflammatory sites, with such cells being mainly responsible for tissue damage.

A further mechanism of viral-induced immunopathology and autoimmunity is molecular mimicry.[33] Molecular mimicry represents shared antigenic epitopes, either B- or T-cell antigen, between the host and virus. This concept originated with streptococci and their association with rheumatic fever. With human autoimmune disease, there is little direct support for viral molecular mimicry; however, some animal models have been used to prove the theoretical case, where a viral antigen is expressed as a self-protein in the islet cells of the pancreas. In this model, subsequent infection with the virus induces diabetes. However, this is not true mimicry and may be more closely related to viral antigen persistence in a model such as Theiler disease.

As discussed previously, the outcome of a T-cell response to a virus may be critically dependent on the balance of the T-cell-type response thus, tissue damage is likely to be more severe and prolonged if $CD8^+$ or Th1 and Th17 $CD4^+$ T cells are predominant. Lesions become milder and may resolve when the balance favors Tregs. Accordingly, therapeutic approaches that can shift the balance of T cells are under trial.

KEY CONCEPTS

Phases of Immunity Affected by Regulatory T Cells (Tregs)

Interference with antigen presentation by dendritic cells
Inhibition of T-cell proliferation
Inhibition of molecules involved in tissue-specific migration of effector cells
Inhibition of T-cell effector functions in lymphoid and nonlymphoid tissues

TRANSLATIONAL RESEARCH OPPORTUNITIES

Reversing T-cell exhaustion in patients suffering from chronic infections or cancer will be a key clinical target in the near future. The discovery of multiple inhibitory receptors on exhausted T cells (*e.g.,* PD-1, LAG-3, 2B4, TIM-3) has provided the opportunity to selectively improve T-cell function through blockade of these inhibitory receptors. This may be combined with blockade of immunosuppressive cytokines (*e.g.,* IL-10) or enhancement of signals stimulatory to the response (*e.g.,* IL-7 therapy), as well as with more traditional antiviral therapies and vaccination. The challenge that lies ahead will be in determining which combination of inhibitory and stimulatory signals will need to be manipulated in different diseases and in different groups of patients.

The design of a new generation of vaccines to target diseases, such as HIV and influenza, may require tailor-made solutions for patients who respond poorly to vaccination or respond improperly, as with adverse effects, such as autoimmune reactions. High-throughput approaches now allow for the generation of a molecular signature of vaccination or infection.[37] Such systems' biology approaches are expected to result in novel screening for immune protection parameters after vaccination. In the near future, this should also assist in the formulation of new vaccines containing key immune activators, such as those that stimulate certain subsets of T cells or induce appropriate homing molecule expression on these cells to direct them to tissues where they are required to mediate protection (*e.g.,* mucosal sites, or skin).

ON THE HORIZON

Pressing Issues in Need of Solutions

Design of new vaccines that induce broadly neutralizing antibodies
Design of new vaccines that induce tissue-resident and circulating memory T-cell subsets
Overcoming immune dysfunction during chronic viral infections for successful viral clearance
Improving the efficacy of vaccines to viruses using systems biology approaches
Therapies for reducing immunopathology during viral infections

In some individuals, viral infections cause mild, or sometimes debilitating, tissue damage. Factors that influence whether a viral infection results in immunopathology varies from individual to individual. These factors include age, the route of infection, preexisting immunity, host genetics, and the host's viral burden or virome. Our knowledge of the influence of these factors on the outcome of viral infection is expected to improve rapidly in the coming decades. Recent advances have shed considerable light on the various proinflammatory and antiinflammatory mediators produced during viral infections. These represent key targets for novel therapies in the near future via the use of small-molecule inhibitors.

CONCLUSIONS

Humans are infected by many pathogenic viruses. In most cases, these infections are controlled by the immune system with limited damage to the host. However, certain viruses, particularly in cases where the host's immune system is impaired, can cause significant damage to the host's tissues. As our understanding of the mechanisms underlying innate immune defenses, antigen presentation, T- and B-cell responses, and Tregs continues to improve, so too does the ability to design better vaccines and therapies to boost the immune control of viral infections. Although this remains a challenging goal, particularly for many human viruses, such as HIV, HCV, and HSV, these rapid advances continue to provide many avenues for further investigation.

MULTIPLE-CHOICE QUESTIONS

1. Many of the most medically important human viruses are associated with persistent viremia, including human immunodeficiency virus (HIV) and hepatitis C virus (HCV). What are the effects of high levels of persisting antigen on the immune response?
   - **A.** Increased killing capacity by cytotoxic T cells
   - **B.** Altered tissue distribution and impaired functions of T cells
   - **C.** Upregulation of T-cell proliferation
   - **D.** Enhanced cytokine production by virus-specific T cells
   - **E.** Reduced expression of coinhibitory molecules by the responding virus-specific T cells

2. Many viral infections can cause immunopathological reactions, such as herpetic stromal keratitis induced by herpes simplex virus. What is a major parameter in the pathogenesis of this disease?
   - **A.** Inhibition of inflammatory cell recruitment into the infected tissues
   - **B.** Recruitment of cytotoxic CD4 T cells that cause ocular pathology
   - **C.** Recruitment and retention of pathogenic CD8 T cells in the late stage of the response
   - **D.** Recruitment and retention of pathogenic Th1 CD4 T cells into the ocular tissues
   - **E.** Reduction in Th17 CD4 T cells in the ocular tissues

3. Immunological memory is a cardinal feature of adaptive immunity to virus infection. Memory T cells can be divided into multiple subsets. Which of the following statements accurately describe the major subsets of memory T cells?
   - **A.** Effector memory T cells migrate through lymphoid tissues, central memory T cells migrate through nonlymphoid tissues, and tissue-resident memory T cells circulate in blood.
   - **B.** Effector memory T cells migrate through nonlymphoid tissues, central memory T cells persist in nonlymphoid tissues, and tissue-resident memory T cells persist predominantly in lymphoid tissues.
   - **C.** Effector memory T cells persist in nonlymphoid tissues and do not enter blood, central memory T cells persist in lymphoid tissues, and tissue-resident memory T cells migrate predominantly through nonlymphoid tissues.
   - **D.** Effector memory T cells migrate exclusively in blood, central memory T cells migrate through lymphoid tissues, and tissue-resident memory T cells are retained in nonlymphoid tissues.
   - **E.** Effector memory T cells migrate through nonlymphoid tissues, central memory T cells migrate through lymphoid tissues, and tissue-resident memory T cells are retained in tissues.

Host Defenses to Intracellular Bacteria

Stephen T. Reece, Stefan H.E. Kaufmann

The evolutionary relationship between humans and bacteria is so intimate that it is impossible to imagine the development of one without the other.[1] Although this coexistence is generally mutually beneficial, clear boundaries do exist between the two and are intensely defended. We tend to think of the human host as the defender and bacteria as transgressors of these boundaries. Evolution of human immunity has been accompanied by evolution of ingenious bacterial mechanisms to not only survive its onslaught but also to manipulate it to enhance survival. This idea is instructively mirrored in the lifestyle of intracellular bacteria. These bacteria actively seek out an environment inside human cells where they can flourish; this is not an easy environment in which to survive. Human cells have developed an ability to differentiate bacterial from host components and direct host cells to clear the invader. The most successful intracellular pathogens have adapted to the intracellular environment of a particular cell target, proliferate only slowly, and can live for long periods completely undetected by the immune system, as we see in the case of the tuberculosis (TB) bacterium *Mycobacterium tuberculosis.* In other instances, for example, in listeriosis, intracellular infection is more explosive, with the rich intracellular environment harnessed to rapidly amplify bacterial growth. In some cases, intracellular bacteria live for a very long time in the human body, sometimes for a person's entire lifetime. A wide spectrum of pathologies ensues from intracellular infection, making most intracellular bacteria highly clinically relevant. Moreover, new concepts on the influence of intracellular bacteria on host cell differentiation point to their ability to change infected cell phenotype to enhance survival.

This chapter evaluates the current interpretation of this fascinating interplay between human and microbe, sheds light on how the human immune system functions, and how cellular phenotype can be molded in cells whose fates were previously believed to be strictly predetermined. Finally, such insights can inform new therapeutic and prophylactic approaches to keep intracellular bacterial infections under control.

BALANCE OF PROTECTION AND PATHOLOGY DEFINES THE CHRONIC NATURE OF INTRACELLULAR BACTERIAL INFECTION

Some bacteria, such as *Listeria monocytogenes,* are fully eradicated once the host immune response has reached its peak activity. Most often, the intracellular habitat provides a protective niche that promotes persistent infection in the face of an ongoing immune response. Here, the bacteria can persist for long periods without causing clinical signs of illness, but bacterial growth can be reactivated to cause disease if the immune response becomes compromised. This occurs in *M. tuberculosis* infection, resulting in disease years or decades after primary infection. In fact, disease need not arise from infection at all. In many regions, for example, the majority of adults harbor *M. tuberculosis* without suffering from clinical disease. However, disease can develop directly after primary infection, during maturation of the immune response, or with regression once the immune response is sufficiently strong. Yet, sterile eradication of the pathogen is rarely achieved: bacteria persist latently, and illness may reemerge at a later time. For example, *Rickettsia prowazekii* may persist for decades after convalescence from typhus to cause Brill-Zinsser disease later.

CLINICAL PEARLS

Distinguishing Clinical Characteristics of Infections With Intracellular Bacteria

Nonsterilizing immunity
Persistent bacteria, sometimes latent infection
Formation of long-lasting tissue granulomas containing low numbers of viable bacteria
Critical role of T cells in protection, role of antibodies less well established but likely to play an as-yet unappreciated role
Critical role of immune response in pathology
Lack of effective vaccines
Host-directed therapies toward enhancing antimicrobial mechanisms while limiting host pathology

Several intracellular bacteria possess components that can profoundly influence the course of disease, for example, the lipopolysaccharides (LPSs) of brucellae and salmonellae. Chronic persistence inside host cells, however, depends on the target cell remaining intact and physiologically active. Accordingly, many intracellular bacteria are of low toxicity and do not have dramatic direct effects on their host. Instead, pathogenesis is largely determined by the immune response. Classic examples of this concept include granuloma liquefaction in acute TB, which severely affects lung function, and eye scarring as a consequence of chronic or recurring *Chlamydia trachomatis* infection that ultimately leads to trachoma.

The survival of intracellular bacteria has major consequences for pathology. Although many intracellular bacteria show some organ tropism, dissemination to other organs frequently occurs, resulting in different disease forms. For example, TB is generally manifested in the lung in 80% of cases, yet many other organs can be affected. In contrast to other *Salmonella enterica* serovars,

TABLE 26.1 Major Infectious Diseases Caused by Intracellular Bacteria

Disease	Pathogen	Prevalence	Incubation Time	Route of Infection	Target Cell
Granulomatous Intracellular Bacteria					
Tuberculosis	*Mycobacterium tuberculosis*	Worldwide	Years (latency after primary infection and disease reactivation) Weeks (miliary TB)	Inhalation of bacteria-containing microdroplets	Macrophage
Leprosy	*Mycobacterium leprae*	South America Africa India Southeast Asia	Years	Smear infection through mucosa/ inhalation	Macrophage Schwann cell
Typhoid fever	*Salmonella enterica* serovars Typhi and Paratyphi	Worldwide	7–10 days	Fecal–oral	Macrophage
Brucellosis	*Brucella* spp.	Worldwide	Weeks to months	Zoonosis; cows, goats, pigs; inhalation, gut, skin abrasion	Macrophage
Listeriosis	*Listeria monocytogenes*	Worldwide	Days to months	Fecal–oral	Macrophage Hepatocyte
Nongranulomatous Intracellular Bacteria					
Legionnaires' disease	*Legionella pneumophila*	Worldwide	2–10 days	Inhalation	Macrophage
Rocky Mountain spotted fever	*Rickettsia rickettsiae*	Western hemisphere	1 week	Tick bite	Vascular endothelial cell Smooth muscle cell
Urogenital infection	*Chlamydia trachomatis* serovars D-K	Worldwide	1–3 weeks	Sexual intercourse	Epithelial cell
Conjunctivitis, trachoma	*Chlamydia trachomatis* serovars A-C	Africa	Conjunctivitis: 1–3 weeks Trachoma: years	Eye	Epithelial cell
Cat scratch disease	*Bartonella henselae* *B. quintana* *B. bacilliformis*	Worldwide	Bacillary angiomatosis Peliosis hepatitis Endocarditis Bacteremia with fever Neuroretinitis: 1–3 weeks	Flea, sandfly, or mosquito bite; animal scratch or bite	Erythrocyte Endothelial cell

the serovars Typhi and Paratyphi are not restricted to the gastrointestinal (GI) tract but are disseminated to internal organs, primarily the liver and spleen. In these cases, the type of clinical disease depends markedly on the infected tissue type.

KEY CONCEPTS

Characteristic Features of Intracellular Bacterial Infections

Persistence of bacteria inside mononuclear phagocytes (*i.e.,* macrophages)
Low to absent bacterial-mediated toxicity to the host
Protection requires cytokine-mediated activation of infected phagocytes
Interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) produced by antigen-specific T cells are key cytokines for protection

INTRACELLULAR BACTERIAL INFECTIONS OF CLINICAL RELEVANCE (Table 26.1)

Granulomatous Infections

Tuberculosis

The major entry of tubercle bacilli into the human body is via inhalation into the lung. These inhaled bacteria are then engulfed by alveolar macrophages, which transport the pathogens to the lung interstitia. Their exact fate after these events is enigmatic. Moreover, most infections in humans result in an asymptomatic carrier state or the so-called latent TB infection (LTBI). Infection with *M. tuberculosis* starts with the so-called Ghon complex, characterized by a caseous lesion in the midlung as well as in the draining lymph nodes. These primary lesions can progress, but their development rarely causes disease directly.[2] Moreover, bacteria from these sites can disseminate to other regions of the lung and systemically, causing disease of the kidneys, liver, and central nervous system (CNS). Containment of the primary lesions, which leads to LTBI, is a function of an effective, predominately cellular antitubercular immune response. Infection of immunocompromised patients, notably those with acquired immunodeficiency syndrome (AIDS), or newborns frequently results in systemic disease (miliary TB). TB represents a major health problem worldwide, including an increasing incidence in many industrialized countries. In 2015, the World Health Organization (WHO) estimated that 10.4 million active TB cases were diagnosed worldwide and close to 1.8 million people died of the disease.[3] The much larger estimated number of 2 billion individuals infected with *M. tuberculosis* well illustrates the dissociation of infection from disease. The emergence of multidrug-resistant strains and extremely drug-resistant strains has complicated treatment with currently available antibiotic therapy, and even when treatment is successful, recurrence of disease can occur. The currently available live whole cell vaccine BCG (Bacille Calmette–Guérin), an attenuated strain derived from the etiological agent of bovine TB *Mycobacterium bovis,* shows only low and variable protection against pulmonary TB.

Leprosy

Mycobacterium leprae is most likely transmitted by contact with patients who shed microorganisms in nasal secretions and lesion exudates. It primarily affects the nerves and the skin, frequently leading to stigmatizing deformities. In skin, bacilli target keratinocytes, histiocytes, and macrophages, whereas in peripheral nerves, Schwann cells are the major target for entry. Leprosy is a spectral disease. The tuberculoid pole is characterized by rigorous T-cell responses, which succeed in restricting microbial growth in well-defined lesions containing few bacilli. In contrast, at the lepromatous pole, bacterial growth is unrestricted and lesions contain abundant bacilli within macrophages lacking signs of activation. Several types of immunosuppression have been implicated in this latter type of disease. Infection of Schwann cells promotes nerve damage and anesthesia. This results in injuries and secondary infections that significantly exaggerate the disease. Despite the success of multidrug therapy in reducing the number of registered leprosy cases worldwide, some 216 000 new cases were reported in 2013. This suggests that active transmission of *M. leprae* is still occurring and that more effective interventions are required to prevent it.[4]

Atypical Mycobacterial Infections

Mycobacterial species present in the environment are typically unable to persist within activated macrophages and thus rarely cause disease in individuals with competent immune status.[5]

As a consequence of human immunodeficiency virus (HIV) infection, however, nontuberculous mycobacteria (NTM), primarily *Mycobacterium avium/Mycobacterium intracellulare,* have gained clinical importance, and these infections are recognized as one of the most common complications of AIDS in industrialized nations.

Mycobacterium scrofulaceum occasionally causes lymphadenitis in children, and *Mycobacterium kansasii* primarily causes infections in older men with preexisting lung disease.

Mycobacterium ulcerans causes a severe subcutaneous infection characterized by chronic skin ulcerations, known as *Buruli ulcer.* This pathology is caused—at least in part—by elaboration of a mycolactone toxin by the bacillus that exhibits highly cytopathic effects.[6] Buruli ulcer is most predominant in West African countries that accounted for most of the 2251 cases reported globally in 2014.[7]

Typhoid or Enteric Fever

Salmonella enterica serovars Typhi and Paratyphi A, Paratyphi B, and Paratyphi C are leading causes of community-acquired bloodstream infections in low- and middle-income countries. The route of transmission is fecal–oral and largely occurs via contaminated water sources. Bacteria are disseminated within mononuclear phagocytes (MPs) from the GI tract to macrophage-rich organs, particularly the liver, spleen, and lymph nodes. Accordingly, typhoid is characterized by systemic symptoms, such as prolonged fever and malaise, with sustained bacteremia, although diarrhea or constipation may also be present. In some cases, an asymptomatic carrier state can persist as a result of chronic infection of the gallbladder, which maintains the environmental reservoir of infection in endemic areas. Typhoid fever remains a major cause of morbidity and mortality, with approximately 21 million new cases and over 190 000 deaths per year worldwide.[8]

Gastroenteritis

S. enterica serovars Typhimurium and Enteritidis, often referred to as nontyphoidal salmonella (NTS), are the major causes of salmonella gastroenteritis in humans, which occurs mainly as a result of the ingestion of contaminated food or water. The bacteria rapidly cross the intestinal epithelia and replicate in the lamina propria, inducing an influx of polymorphonuclear neutrophils (PMNs), which is generally sufficient to resolve the infection within 7 days. In rare cases, bacteria enter the bloodstream and cause systemic bacteremia, most notably in patients with AIDS, where death can occur as a result of septic shock.[8]

Listeriosis

Listeriosis monocytogenes is increasingly recognized to cause foodborne gastroenteritis. Clinical listeriosis affects mainly pregnant women, older adults, fetuses, and neonates. Disease manifestations are most severe in patients with a compromised immune system, in whom the CNS becomes involved and fatal bacteremia can result. Additionally, as these bacteria are able to cross the placenta, listeriosis is a major cause of perinatal and neonatal disease, typically resulting in abortion. Listeria outbreaks are sporadic with low incidence but high fatality and affect high-income countries, such as the United States.

Brucellosis

Brucellosis is the most common global zoonosis of humans with approximately 500 000 cases per year.[9] It is caused by *Brucella abortus, B. melitensis,* or *B. suis,* which primarily infect cows, goats, and pigs, respectively. The bacteria are transmitted to humans via inhalation, through abraded skin or the GI tract. Lesions are primarily found within macrophage-rich tissues, especially the spleen and bone marrow. Human brucellosis is characterized by systemic symptoms, particularly undulant fever. Although the disease often remains subclinical, it becomes chronic in some patients, and relapses and remissions may occur. Interest in brucellosis has increased in the last 5 years because of elevated levels of detection resulting from better surveillance.

Lymphogranuloma Venereum

Lymphogranuloma venereum (LGV), a sexually transmitted disease, is highly prevalent in Africa, Southeast Asia, and Latin America. LGV has recently emerged as infection of sexually active homosexual men in Europe and the United States. It is caused by the L1, L2, and L3 serotypes of *Chlamydia trachomatis,* which are disseminated from the urogenital tract to local lymph nodes and then to skin. Accordingly, LGV is characterized by lymph node swelling and skin lesions, which are accompanied by systemic complications.[10]

Melioidosis

Burkholderia pseudomallei is a gram-negative bacillus and the causative agent of melioidosis, endemic in Southeast Asia and Northern Australia. The disease can be acquired through inhalation and ingestion or through cuts in the skin. Susceptible hosts can suffer abscess formation in multiple organs and, in some cases, disseminated infection, resulting in septic shock accompanied by pneumonia. There are an estimated 165 000 cases of melioidosis per year globally, resulting in approximately 89 000 deaths.[11]

Tularemia

This rare zoonosis in humans caused by *Francisella tularensis* is mainly found in rabbits and has recently gained wider recognition because of its potential for dual use.[12] Infection can be spread to humans via contaminated animals or tick bites. This gram-negative bacterium survives in macrophages and primarily causes acute pneumonia as well as skin sores, with subsequent involvement of lymph nodes.

Nongranulomatous Infections

Legionnaires' Disease or Legionellosis

Legionnaires' disease is caused by *Legionella pneumophila,* an environmental bacterium that persists within amoeba living in water reservoirs (*e.g.,* air-cooling systems), from where it is spread aerogenically. Infection is exacerbated by a compromised immune status. Characteristically, Legionnaires' disease presents as atypical pneumonia associated with general symptoms and is complicated by extrapulmonary infection, renal failure, and lung abscesses. Cases of Legionnaires' disease in the United States increased from 0.39 to 1.36 per 100 000 people from 2000 to 2011.[13]

Chlamydial Urethritis, Cervicitis, and Conjunctivitis

C. trachomatis serovars D–K enter and persist in epithelial cells of the urogenital tract, causing cervicitis and urethritis. In women, infertility can develop as a result of chronic or recurrent infection. In neonates, congenital infection during birth may result in conjunctivitis and pneumonia. Urogenital infections by chlamydiae occur worldwide and are now considered the most common sexually transmitted bacterial disease, with an estimated 100 million new infections occurring annually.[14]

Trachoma

Smear infections of the eye with *C. trachomatis* serovars A, B, and C cause inclusion conjunctivitis. As a consequence of multiple chronic infections and of the resulting immune response, scars develop that eventually injure the cornea, leading to trachoma. Approximately 84 million people are infected with *C. trachomatis* worldwide, 7.6 million of whom suffer from visual impairment.[15]

Chlamydia Pneumoniae

C. pneumoniae (formerly known as *C. trachomatis* TWAR strain) is the cause of mild respiratory disease in young adults and may cause serious infections in older, more debilitated patients. Atypical pneumonia may also be caused by *Chlamydia psittaci,* although this zoonosis, transmitted by birds, is relatively rare.

Typhus

Rickettsia prowazekii, R. typhi, and *R. tsutsugamushi* cause diseases of varying severity.[16] They are transmitted by arthropods and infect vascular endothelial cells at the site of an insect bite or scratch, causing skin reactions. Subsequently, pathogens are disseminated to the central organs, and more general symptoms develop. Globally, typhus is of minor importance.

Rocky Mountain Spotted Fever, Ehrlichiosis

Rocky Mountain spotted fever is caused by *Rickettsia rickettsii.* Infection of the vascular endothelium leads to systemic symptoms and skin manifestations that may be followed by shock and neurological complications.[16] Worldwide, this disease, as well as Mediterranean spotted fever caused by *Rickettsia conorii,* is of minor importance; as is probably Ehrlichiosis, a newly emerging zoonosis transmitted by ticks and caused by various *Ehrlichia* spp., mainly *E. chaffeensis.*[17] Disease manifestations include generalized symptoms, such as fever and muscle pain.

Bartonella

Bartonella spp. represent gram-negative facultative intracellular pathogens transmitted by insect vectors, such as fleas, sandflies, and mosquitoes.[18] The most clinically relevant species are *B. henselae, B. quintana,* and *B. bacilliformis. B. henselae* causes cat scratch disease (CSD) resulting in local lymphadenopathy in the lymph node draining the scratch site accompanied by fever, headache, and splenomegaly. Oculoglandular involvement (Parinaud syndrome), encephalopathy, neuroretinitis, or osteomyelitis can occur, albeit in rare cases. In immunosuppressed patients, bacillary angiomatosis and peliosis can occur, characterized by pseudotumoral proliferation of endothelial cells. Bacteria persist within erythrocytes with the intracellular location providing a protective niche.

GRANULOMA PATHOLOGY AS HALLMARK OF INTRACELLULAR BACTERIAL INFECTION

KEY CONCEPTS

Balance of Protection and Host Pathology in Granulomas

- Macrophage activation results in bacterial death (protective)
- Intracellular bacterial killing by "killer molecules" from T cells (protective)
- Lysis of infected macrophages by T cells results in release of bacteria and killing by more effective effector cells (protective) or bacterial dissemination (pathogenic)
- Development of central necrosis in granulomas results in death of tissue and bacteria (protective/pathogenic)
- Fibrotic encapsulation of granuloma results in containment of infection (protective)
- Overexuberant tissue fibrosis and necrosis (pathogenic)
- Liquefaction of central necrotic tissue in granulomas results in bacterial replication, cavity formation, and transmission of bacteria (pathogenic and contagious)

A characteristic feature of many infections caused by intracellular bacteria is the eventual need for tissue remodeling by the host at the site of infection. Granulomas are the result of an inability to rapidly clear host tissue of intracellular bacteria and represent a fascinating site of the host–pathogen interface (Fig. 26.1). The longevity of the granuloma depends directly on the continuous presence of the microbial pathogen, and the lesion generally disappears after its sterile eradication. Granulomas form the focus of the coordinated cross-talk between different types of T cells, B cells, and infected and uninfected mononuclear phagocytes (MPs) and dendritic cells (DCs). Even if the immune system fails to completely eliminate bacteria inside the granuloma, the latter performs a protective function by containing microbes within distinct foci and preventing their dissemination. At the same time, the granuloma can be detrimental to the host because it can interfere with physiological organ functions.[19] More detailed study of cellular phenotype within granulomas is starting to establish how cellular differentiation is orchestrated and how the granuloma develops.

Granulomatous lesions are generally initiated by nonspecific inflammatory signals mediated by bacterial products, chemokines, and proinflammatory cytokines that are produced by endothelial cells and MPs at the site of infection. Inflammatory phagocytes (of both monocytic and granulocytic origin) are attracted to the site of microbial replication, and an infiltrative, sometimes exudative, lesion develops. Following the accumulation and

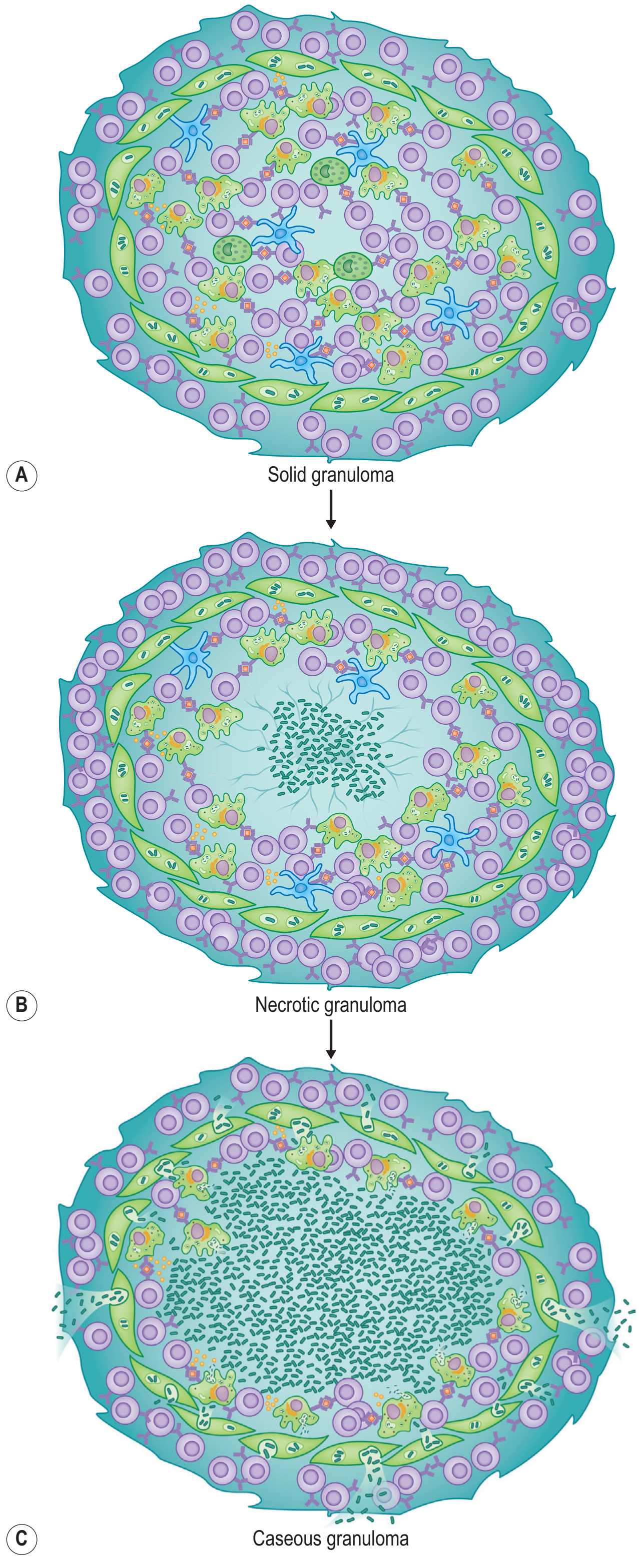

FIG 26.1 **Development of Granuloma Pathology and Implications for Tuberculosis (TB).** This figure depicts three distinct yet continuous stages of granuloma pathology in the lung due to *Mycobacterium tuberculosis* infection. (A) Solid granuloma: Composed largely of T cells and infected and uninfected MPs. These granulomas are defined by a lack of central necrosis and likely are representative of an ability to control *M. tuberculosis* replication. (B) Caseous/necrotic granulomas: These structures contain a central region of demarcated necrotic cell death. Bacteria are often detected within the caseous necrotic region and in proximal cells, notably mononuclear phagocytes (MPs). Since calcified caseous granulomas containing few bacteria have been observed, development of central necrosis may be a consequence of antibacterial mechanisms resulting in sacrifice of host cells to contain infection. (C) Cavity formation: These structures result from inability of caseous granulomas to contain bacterial replication. The acellular necrotic region, containing a large number of extracellular bacteria, increases in size and can liquefy and empty into the lung airways, resulting in transmission of viable bacteria via cough. Therefore granuloma formation is central to human-to-human spread of TB. Dissemination of bacteria through the bloodstream results in disease manifestation in other organs, such as the meninges and the urinary bladder.

activation of increasing numbers of MPs and DCs, this lesion takes an increasingly structured granulomatous form. A significant number of B cells is also found, which seem to influence granuloma morphology. Once specific T cells have been attracted to the lesion, it transforms into a productive granuloma that provides the most appropriate tissue site for antibacterial protection. Here, activation of MPs by interferon-γ (IFN-γ) and tumor necrosis factor-α (TNF-α) inhibits microbial growth. However, unbridled macrophage activation can have tissue-damaging effects, and mechanisms within the granuloma tightly regulate these effects. Eventually, the granuloma is encapsulated by a fibrotic wall, and its center becomes necrotic. Both tissue reactions are primarily protective, the former by promoting bacterial containment and the latter by reducing the nutrient and oxygen supply to the pathogen. The combined effects of chronic macrophage activation, persistence of intracellular bacteria, and hypoxia likely lead to enhanced cell death in the center of granulomas, resulting in the formation of a caseum. Caseation may favor the local replication of normally facultative intracellular bacteria in the cellular detritus, as well as microbial dissemination to distant tissue sites and to the environment to transmit infection. Hypoxia also has pronounced effects on enzyme functions that can dictate macrophage phenotype.

THE INTERDEPENDENCE OF INNATE AND ADAPTIVE IMMUNITY IN PROTECTION AGAINST INTRACELLULAR BACTERIA

Innate Immune Mechanisms as First-Line Defense

The interaction between host cell and pathogen that defines the intracellular lifestyle consists of a number of different layers. The first layer that differentiates intracellular bacteria from other bacteria, notably commensal bacteria that colonize the host but do not cause infection, is that of host cell entry. Extracellular bacteria are typically engulfed by professional phagocytes, which include tissue macrophages, DCs, and PMNs. This uptake is enhanced by host components of the complement system and antibodies, which bind to complement receptors (CRs) and Fc receptors, respectively, on professional phagocytes.[20] *M. tuberculosis* actively targets macrophages, where it must counteract numerous antimicrobial mechanisms operative in these cells (see below). Intracellular bacteria also use elaborate mechanisms to enter nonprofessional phagocytes, by which they must subvert host endocytic processes that are normally engaged in traffic of cellular cargoes. In some cases, this provides a less hostile environment because of their inability to efficiently mobilize antibacterial effector mechanisms. *Bartonella* spp., unique among intracellular bacteria, can enter red blood cells, thus allowing transmission via blood-sucking insect vectors. This represents a particularly advantageous niche as red blood cells lack the machinery to drive the adaptive immune responses required for protection. Entry into nonphagocytic host cells requires bacteria to induce their own internalization. Bacteria that colonize the GI tract (*i.e., L. monocytogenes* or salmonellae) or mucosal membranes of the urogenital tract (*i.e., C. trachomatis*) must mediate tight adhesion to the host cell membrane and be capable of mediating the uptake process. Broadly, two processes are utilized by bacteria to induce uptake into a nonphagocytic cell. The "zipper" mechanism is mediated by binding of a bacterial cell surface protein binding a cognate receptor on the host cell membrane. *L. monocytogenes* entry into intestinal epithelial cells depends on engagement of InlA to E-cadherin to mediate uptake.

Salmonellae and *C. trachomatis* use a "trigger" mechanism to induce internalization and inject multiple factors into the host cell cytoplasm to mediate uptake. These proteins are delivered by the needle-like structures that form part of bacterial type III secretion systems (T3SSs). These injected proteins then target host proteins involved in host cell signaling and actin remodeling to induce bacterial entry. The *C. trachomatis*–secreted proteins Tarp, CT166, and CT694 reversibly stimulate the Rho-family guanosine triphosphatase (GTPase) Rac1 to trigger internalization. Similarly, salmonellae inject T3SS factors to stimulate the Rho-family GTPases Cdc42 and Rac1. The success of these mechanisms of induced uptake enables intracellular bacteria to persist inside diverse cell types. *Rickettsia* spp., *C. trachomatis, M. leprae,* and *L. monocytogenes* ultimately target vascular endothelial cells, epithelial cells, Schwann cells, and hepatocytes, respectively, as their preferred intracellular habitats.

To prevent intracellular infection, the host depends on its ability to discriminate between host and bacterial molecules. As already mentioned, bacteria targeting the intracellular environment often do so via mucosal surfaces already populated by commensal organisms (the microbiome) that do not alert host defenses. The host must, therefore, discriminate between commensal and pathogenic bacteria via recognition of conserved molecular motifs of bacteria, named *pathogen-associated molecular patterns* (PAMPs). This occurs via host receptors broadly defined as pattern recognition receptors (PRRs, Table 26.2). The best-characterized group of PRRs is that of the so-called Toll-like receptors (TLRs). The TLR system constitutes an innate scanning mechanism of microbial pattern recognition to distinguish between a wide spectrum of bacteria and viruses. TLRs are present as homo- or heterodimers on the plasma membrane or within intracellular endosome/phagosome compartments.[21] PAMPs of bacterial origin comprise di- and triacyl lipoproteins, LPSs, and flagellin, which are recognized by TLR-2/6, TLR-2/1, TLR-4/4, or TLR-5/5, respectively. The vast array of mycobacterial cell wall lipids, such as lipoarabinomannan (LAM), trehalose dimycolate (TDM), and phosphatidylinositol mannosides (PIMs) bind either TLR-2 or TLR-4. Lipoteichoic acid (LTA) of gram-positive bacteria is recognized by TLR-2. TLR-9 binds low-methylated bacterial DNA containing CpG motifs within endosomes.

TABLE 26.2 Major Pattern Recognition Receptors Involved in Sensing of Intracellular Bacteria

Pattern Recognition Receptor	Location	Ligand
Toll-Like Receptors		
TLR1	Plasma membrane	Triacyl lipoprotein
TLR2	Plasma membrane	PGA, porins, LAM
TLR4	Plasma membrane	LPS
TLR5	Plasma membrane	Flagellin
TLR6	Plasma membrane	Diacyl lipoprotein
TLR7 (human TLR8)	Endosome	ssRNA
TLR9	Endosome	CpG DNA
Scavenger Receptors		
SR-A	Plasma membrane	LPS, LTA, CpG DNA, proteins
MARCO	Plasma membrane	LPS, proteins
CD36	Plasma membrane	Diacyl lipoprotein
LOX-1	Plasma membrane	Protein
SREC	Plasma membrane	Protein
C-Type Lectins		
DC-SIGN	Plasma membrane	LPS, ManLAM, capsular polysaccharide
MINCLE	Plasma membrane	Mycobacterial cord factor: TDM
NOD-Like Receptors		
NOD1	Cytoplasm	D-glutamyl-meso-diaminopimelic acid
NOD2	Cytoplasm	MDP
NLRP1	Cytoplasm	MDP
NLRP3	Cytoplasm	RNA, LPS, LTA, MDP
NLRC4	Cytoplasm	Flagellin
Naip5	Cytoplasm	Flagellin
AIM2-Like Receptors		
AIM2	Cytoplasm	dsDNA
IFI16	Cytoplasm	dsDNA
STING/cGAS Pathway		
cGAS	Cytoplasm	dsDNA

Note: We omit PRRs (*e.g.,* TLR3, which binds viral produced double-stranded RNA) not classically associated with intracellular bacteria. AIM2, absent in melanoma-2; CD36, cluster of differentiation 36; CpGDNA, cytosine-phosphatidyl-guanine DNA; DC-SIGN, dendritic cell–specific intercellular adhesion molecule-3-grabbing nonintegrin; dsDNA, double-stranded DNA; LAM, lipoarabinomannan; LOX-1, lipoxygenase-1; LPS, lipopolysaccharide; LTA, lipoteichoic acid; ManLAM, mannose lipoarabinomannan; MARCO, macrophage receptor with collagenous structure; MDP, muramyl dipeptide; MINCLE, macrophage-inducible C-type lectin; NLR, NOD-like receptor; NOD, nucleotide-binding domain; PGA, peptidoglycans; PRR, pattern recognition receptor; SR, scavenger receptor; ssRNA, single-stranded RNA; SREC, scavenger receptor expressed by endothelial cell-I; TDM, trehalose dimycolate; TLR, Toll-like receptor.

Scavenger receptors and C-type lectins are also PRRs and function at the cell membrane.[22] Scavenger receptors were first defined by their ability to transport modified forms of low-density lipoproteins inside cells, indicating their ability to also interact with host molecules. However, receptors, such as SR-A, MARCO, CD36, LOX-1, and SREC, can bind a wide array of bacterial molecules, such as lipids, CpG DNA, and proteins (see Table 26.2 for binding specificities). SR-A is important for clearance of extracellular bacteria from the spleen and liver. MARCO expressed on alveolar macrophages is implicated in clearance of pneumococcal bacteria preventing pneumonia. C-type lectins are similarly membrane-expressed and include DC-specific intercellular adhesion molecule–grabbing nonintegrin (DC-SIGN); mannose receptor; dectin-1; dectin-2, which chiefly recognize fungal components; and MINCLE, which recognizes trehalose dimycolate (TDM), the cord factor of *M. tuberculosis.*

It has been suggested that scavenger receptors and C-type lectins are required to bind and internalize the bacillus, whereas it is primarily the TLRs that discriminate between the pathogens and initiate the necessary intracellular signaling events. It should, however, be noted that intracellular signaling events can also be triggered by other interactions, such as ligand binding to macrophage mannose receptor (MMR), dectin 1, or DC-SIGN. Far from a one-ligand, one-receptor binary mechanism of sensing and signaling, PRRs often collaborate to produce multiprotein complexes. CD14, MD2, and TLR4 collaborate for LPS sensing and signaling. Similarly, MARCO and TLR2 synergize to recognize TDM. To allow signaling, these complexes interact with adaptor proteins containing immunoreceptor tyrosine-based activation motif (ITAM)-like or Toll/interleukin-1 receptor (TIR) domain motifs. TLR signaling occurs via the adaptor proteins MyD88, TIRAP/Mal, and Trif. These molecules then orchestrate a downstream signaling cascade, which culminates in induced patterns of gene transcription that mediate innate and, ultimately, adaptive immune mechanisms that aim at combating the intracellular bacteria.

The cellular cytoplasm is monitored for presence of molecules of bacterial origin by a further group of PRRs, the nucleotide oligomerization domain protein-like receptors (NLRs). These molecules are characterized by presence of a nucleotide-binding domain and leucine-rich repeat motifs. Molecules from this group recognizing bacterial components are nucleotide-binding oligomerization domain (NOD)–containing proteins NOD1 and NOD2, NOD-like receptor P1 (NLRP1), NLRP3, and Naip5. Other cytosolic PRRs include the absent in melanoma-2-like receptor (ALR) family, cyclic guanosine monophosphate–adenosine monophosphate (cGMP-AMP) synthase (cGAS), and stimulator of interferon (IFN) genes (STING), all of which can be activated by bacterial DNA (see Table 26.2).

Engagement of NLRs and ALRs leads to activation of the multiprotein complex called the *inflammasome,* leading to cleavage of pro-IL-1β and pro-IL-18 to produce their active forms. In addition, activation of the NLRs, NOD1, and NOD2 results in inflammatory cytokine secretion. Certain PRRs are also receptive to certain endogenous “danger” signals produced by tissues undergoing stress, damage, or cell death. These signals are triggered by self-proteins, named *danger-associated molecular patterns* (DAMPs), include endogenous heat shock proteins, host nucleotides, and the chromatin component HMGB1. Therefore PRRs mediate signals not only emanating from intracellular bacteria but also from host cells damaged by the infection process. Understanding how PAMP and DAMP PRR signaling meshes to produce a coherent disease-specific output remains an exciting challenge for future research.

As already alluded to, the culmination of PRR collaborative sensing and signaling is the induction of inflammatory genes that induce innate immune mechanisms and, subsequently, the mobilization of the adaptive immune response. These include cytokines that act both locally and systemically and are important mediators of protection against intracellular bacteria via specific signaling through engagement of host cell surface receptors. Such engagement mobilizes both critical mechanisms of host protection and orchestration of adaptive immune responses.

Macrophage Training by Epigenetic Mechanisms

Following infection with, for example, *M. tuberculosis,* macrophages express elevated effector mechanisms over long periods. More recent findings have revealed that this is caused, at least in part, by epigenetic changes that are induced in MPs during infection. Similar training can also occur after vaccination with live vaccines. Moreover, BCG vaccination was shown to induce changes in methylation patterns of the *NOD2* gene in humans. These epigenetic changes led to increased production of proinflammatory cytokines by MPs, namely, TNF and IL-1β, a tendency that persisted for 3 months after vaccination. Furthermore, this enhanced innate immunity led to increased resistance not only against *M. tuberculosis* but also against other bacterial pathogens. Indeed, it has been speculated that epigenetic alterations in MPs following vaccination are responsible for the nonspecific reduction of mortality in BCG-vaccinated infants in resource-poor regions of the world.[23]

Cytokines as Mediators of Defense Against Intracellular Bacteria

We have already mentioned that a range of cytokines are induced by the signaling mechanisms that result from engagement of PRRs. These serve by both enhancing intracellular mechanisms of bacterial killing and mobilizing adaptive immune responses, representing the next layer of host defense. Because these responses allow an amplification of the initial innate immune responses, they must be carefully regulated by the host to prevent extensive tissue pathology. In fact, we might view the development of a granuloma as the sequela of a balance between bacterial killing mechanisms and the need to restrict tissue pathology orchestrated by adaptive immunity. At the onset of infection, initial cytokine secretion occurs in the cell type that initially encounters intracellular bacteria and on initiation of signaling cascades by PRRs. These small molecules can act locally and systemically to directly instruct cells, to produce antibacterial molecules, to combat intracellular infection, and to both increase numbers of immune cells and direct the composition of the cellular infiltrate that will ultimately attempt to resolve intracellular bacterial infection. Cytokines are ultimately produced by multiple cell types, including adaptive T cells, B cells, unconventional T cells, MPs, DCs, PMNs, and even epithelial and endothelial cells. We will first consider the hierarchy by which these cytokines act in the control of intracellular bacterial infection and the antibacterial mechanisms they regulate. We will then return to the generation and regulation of the cells that produce them.

IFN-γ, TNF-α, IL-12, and IL-18

By far, the cytokine with the clearest demonstrable potency against intracellular bacteria is IFN-γ. Extensive studies on the activation of antibacterial effector functions in macrophages have revealed a central role for IFN-γ. Accordingly, IFN-γ neutralization with antibodies, or deletion of the IFN-γ gene by homologous recombination, markedly exacerbates infectious diseases, such as

KEY CONCEPTS

T Cell–Mediated Mechanisms Underlying Protection

- IFN-γ- and TNF-α-mediated activation of phagocytes to kill bacteria by means of:
  - Reactive oxygen intermediate (ROI) and reactive nitrogen intermediate (RNI)
  - Delivery of lysosomal hydrolytic enzymes and antimicrobial peptides to the bacteria-containing phagosome
  - Autophagy
  - Formation and maintenance of granulomas
- T cell–mediated response controls but does not eradicate the pathogen

listeriosis, TB, or typhoid in experimental animals. For macrophages harboring intracellular bacteria, namely, *M. tuberculosis*, signaling with IFN-γ is a game-changer, summoning infected macrophages to escalate antimicrobial mechanisms. The action of TNF-α appears to augment IFN-γ and is also important in control of intracellular infection. This has been demonstrated in humans through use of blocking of TNF-α by antibodies as antiinflammatory therapy. Such treatments can activate TB in individuals with LTBI. Despite this, these potent protective effects of IFN-γ and TNF-α come at a price. The need to kill intracellular bacteria often leads to death of the host cell as collateral damage. In part, the host manages this by controlling how the cell dies. Excessive TNF-α leads to less regulated necrotic cell death, benefiting *M. tuberculosis*. For this reason elaborate host mechanisms have evolved to maintain TNF-α at optimal levels to control infection. The host enzyme leukotriene A4 hydrolase (LT4H) catalyzes synthesis of a highly proinflammatory lipid leukotriene B4. In the event of enzyme deficiency, an antiinflammatory lipid lipotoxin A4 accumulates that counteracts effects of TNF-α. Two common variant promoters control expression of *LT4H* in humans, and homozygotes are associated with either high or low inflammation. In contrast, the heterozygotes show a balanced response to TNF-α associated with resistance against TB. Such a finding strongly suggests that genetic mechanisms can maintain an optimal level of TNF-α responsiveness of cells harboring intracellular bacteria, namely, *M. tuberculosis*. A central antimicrobial mechanism stimulated by IFN-γ and TNF-α is production of reactive nitrogen intermediates (RNIs) via the induction of nitric oxide synthase (NOS)2 and reactive oxygen intermediates (ROIs) via activation of nicotinamide adenine dinucleotide phosphate (NADPH)–dependent oxidative burst. IFN-γ also promotes antimicrobial effects associated with vitamin D and induces autophagy, a mechanism that plays an important role in host defense. It is now clear that the production of IFN-γ depends on prior activation by IL-12 and/or IL-18. IL-12, in concert with TNF-α, induces a cytokine loop resulting in the production of IFN-γ, which sustains the production of IL-12 and IL-18. These observations have been extended to humans, in whom mutations that affect IFN-γ signaling cause susceptibility to *M. tuberculosis* and salmonellae, as well as to BCG and commonly nonpathogenic mycobacteria, and are termed *mendelian susceptibility to mycobacterial disease* (MSMD). The mutations are located in genes that include *IL12B* and *IL12RB,* which encode subunit β of the IL-12 cytokine and its receptor, respectively, and *IFNGR1* and *IFNGR2,* which encode the IFN-γ receptor. Further unraveling of the molecular basis of human genetic susceptibility to intracellular bacterial infection will continue to illuminate our understanding of how immunity is similarly orchestrated across multiple infectious diseases.

Proinflammatory Cytokines and Phagocyte Attraction

The recruitment of more phagocytes to the site of infection represents a vital process in the resolution of infection. Phagocyte recruitment is achieved via the secretion by MPs and endothelial cells of cytokines of the IL-1 family, TNF-α, IL-6, and chemokines. Signaling via IL-1 cognates is considered closely related to that of the TLRs because of the close homology of the cytoplasmic domains of TLRs and IL-1 family receptors. The most studied member is IL-1β, which, in synergy with chemokines and TNF-α, increases the expression of adhesion molecules on the vascular epithelium, thereby promoting extravasation of the inflammatory cell infiltrate into infected tissues. Chemokines are a family of structurally related proteins. The positions of the first two cysteine residues in the protein sequence have been used to divide chemokines into four subfamilies: CC (MIP-1β, MCP-1, MCP-2, MCP-3), CXC (MIP-2, IL-8), C (lymphotactin), and CX3C chemokines (fractalkine), where C represents cysteine and X represents any amino acid other than cysteine. These molecules are critical in controlling the migration of PMNs (IL-8) and monocytes (MCP-1, also known as CCL2) from the bloodstream to infected tissue.[24] Recently, the role of chemokines in intracellular infections has been increasingly appreciated, for example, with mice lacking the receptor for CCL2 being deficient in their ability to clear listeria infection. It has been suggested that in the early stages of infection, *M. tuberculosis* exploits a delay in the mobilization of T-cell immunity to recruit MPs to the site of infection, which preferentially serve as habitat because of a lack of local IFN-γ from T cells. Moreover, *M. tuberculosis* is thought to infect the relatively sterile lower airways. The lack of commensal bacteria could mean that *M. tuberculosis* uses cell surface phenolic glycolipid (PGL) to signal epithelial cells to produce the chemokine CCL2 in the absence of signaling via other PAMPs.[25] This mechanism then recruits MPs that are more permissive for bacterial growth than those recruited by a more "global" MyD88-dependent signaling of TLRs, requiring coengagement of PAMPs on commensal bacteria that are more abundant in the upper airways. The initial macrophage infiltrates could play an important role in early granuloma development.

Cytokine-Induced Host-Protective Mechanisms

Effector Molecules

Activation of a membrane-bound NADPH oxidase by stimulation with IFN-γ or immunoglobulin G (IgG) initiates an oxidative burst that generates the ROIs O_2^-, H_2O_2, OH^-, $^1O_2$, and •OH radical (Table 26.3).[26] In human PMNs and blood monocytes that possess myeloperoxidase, ROI activity is further augmented by the formation of hypochlorous acid. Oxidation and/or chlorination of bacterial lipids and proteins result in their inactivation and subsequent bacterial killing. The importance of ROIs in antibacterial defense is underlined by recurrent infections in patients whose phagocytes fail to generate an oxidative burst. Nitric oxide synthase 2 (NOS2) is an inducible cytosolic enzyme in professional phagocytes that delivers NO to the phagolysosome harboring bacteria while consuming O_2 and L-arginine. NO is further oxidized to NO_2^- and NO_3^-. Nitrification and/or oxidation then inactivates bacterial molecules needed for bacterial growth.[27] The formation of •NO is catalyzed by NOS2, which is promoted by both immunological stimuli, such

TABLE 26.3 **Antibacterial Effector Mechanisms of Activated Macrophages and Corresponding Microbial Evasion Strategies**

Macrophage Effector Mechanism	Microbial Evasion Strategy
Production of ROIs	Uptake via complement receptors; production of ROI detoxifying molecules (superoxide dismutase, catalase); bacterial ROI scavengers (phenolic glycolipids, sulfatides, lipoarabinomannans)
Production of RNIs	Inhibition of phagosome maturation via blockage of H^+ATP pump, indirect effect of ROI-detoxifying molecules
Autophagy, intraphagolysosomal killing	Egression into cytoplasm; Resistant cell wall
Phagosomal acidification, phagosome–lysosome fusion	Inhibition of phagosome maturation
Defensins	Modification of cell wall lipid A to resist defensins
Reduced iron supply (transferrin receptor downregulation, lipocalins)	Expression of microbial siderophores to increase iron uptake
Tryptophan degradation	Upregulation of bacterial tryptophan synthesis

ATP, adenosine triphosphate; ROI, reactive oxygen intermediate; RNI, reactive nitrogen intermediate.

as IFN-γ and TNF, and microbial products, such as LPS, lipoteichoic acid, and mycobacterial lipids. RNIs exert their bactericidal activity by destroying iron-/sulfur-containing reactive centers of bacterial enzymes and by synergizing with ROIs to form highly reactive peroxynitrite ($ONOO^-$). Despite being highly effective in killing intracellular bacteria, NO production relies on a continuous supply of L-arginine, which becomes limited because of competition with another macrophage enzyme, Arginase-1 (Arg-1). Arg-1 metabolizes L-arginine to produce urea and ornithine and demonstrates antiinflammatory activity. The competitive function of Arg-1 likely regulates collateral tissue damage caused by overexuberant RNIs. The final downstream product of NOS2 activity is citrulline, which is recycled to L-arginine by the enzymes argininosuccinate synthase (Ass1) and argininosuccinate lyase (Asl). A mouse deficient in macrophage Asl activity is unable to control mycobacterial infection, highlighting the importance of this recycling pathway. The central role of NOS2 in protection against intracellular bacteria is well established in murine models of infection. Whether NOS2 plays a similarly central role in humans is still unclear. Defensins are small lysosomal polypeptides that are microbicidal at basic pH and are particularly abundant in phagocytes. These include granulysin, present in granules of human natural killer (NK) and cytolytic T (CTLs) cells,[28] and cathelicidin, which is regulated by vitamin D in a TLR-dependent manner and is converted by cleavage to the antimicrobial peptide LL-37.

Apoptosis and Autophagy

Apoptosis is a highly regulated form of cell death that is critical for control of cell turnover, a vital process for tissue homeostasis.[29] Macrophage apoptosis also constitutes a defense mechanism, allowing removal of phagocytes containing intracellular bacteria without the need to generate significant inflammation. Apoptosis, in contrast to cellular necrosis, results in cell death without permeabilization of the host cell membrane. The process can be triggered by TNF-α signaling and augmented by IFN-γ, resulting in activation of cellular caspases, mitochondrial membrane permeability, and cytochrome c release. These processes result in cellular disintegration and generation of apoptotic bodies that are engulfed and digested by neighboring phagocytic cells. Apoptosis is protective against *L. monocytogenes* and *Salmonella* spp. and is inhibited by *M. tuberculosis,* which promotes necrotic cell death of infected cells to its benefit via mitochondrial membrane damage and by caspase-independent mechanisms during conditions of high bacterial burden in macrophages. Noninfected cells engulf bacterial antigens associated with vesicles produced by apoptotic cells. Apoptosis as a prerequisite for this pathway is induced by many intracellular bacteria, including salmonellae, mycobacteria, and listeriae. This cross-presentation pathway in infections with intracellular bacteria adds an essential function to the physiological role of apoptosis in the maintenance of tissue integrity and growth.

Upon signaling via IFN-γ, autophagy, a process common to all cells for removal of dysfunctional or damaged cellular organelles, can be harnessed to dispose of intracellular *L. monocytogenes* and *M. tuberculosis* in a process termed *xenophagy.* Signaling via members of the immunity-related guanosine triphosphatase (GTPase) family (IRG family) and the guanylate-binding protein family, TLR2 and TLR4 engagements and the active form of vitamin D_3 all act to augment xenophagy. Formation of double-membrane autophagosomes that mature analogously to the phagosomal pathway and fuse with lysosomes that degrade bacteria contained within. The importance of this process is highlighted by polymorphisms in one of the three IRG families of genes in humans, *IRGM,* being associated with susceptibility to TB. Recently, a host-encoded microRNA, miRNA-155, was shown to potentiate xenophagy during intracellular mycobacterial infection by targeting an endogenous inhibitor of autophagy, Ras homologue enriched in brain (Rheb) by suppressing Rheb expression.

Nutrient Deprivation

Deprivation of required nutrients to intracellular bacteria is also a strategy employed by the host, markedly so within infected macrophages. Tryptophan degradation is achieved by the enzyme indoleamine 2,3-dioxygenase (IDO), which degrades tryptophan to kynurenine (see Table 26.3). This reaction is induced by IFN-γ in both MPs and IFN-γ-responsive nonprofessional phagocytes and inhibits the growth of *C. psittaci* and *C. trachomatis* inside human macrophages and epithelial cells. Similarly, augmentation of NOS2 by IFN-γ and TNF-α depletes intracellular L-arginine, also required for growth of intracellular bacteria.[20]

EVASION FROM, INTERFERENCE WITH, AND RESISTANCE TO MICROBIAL KILLING

Strategies Against Toxic Effector Molecules

Many intracellular bacteria have exploited successful strategies against macrophage effector mechanisms (see Table 26.3). One mechanism of evasion is determined by the receptor that is used for pathogen entry into the host cell. Internalization via CRs inhibits the production of IL-12, a cytokine critical in facilitating macrophage activation. Engulfment by this receptor also bypasses activation of the oxidative burst, thereby avoiding ROI production. Similarly, engaging mismatch repair (MMR) and DC-specific intercellular adhesion (DC-SIGN) molecules for uptake triggers secretion of the suppressive cytokines IL-10 and TGF-β. Several intracellular bacteria also produce ROI detoxifiers, including superoxide dismutase and catalase, which nullify oxygen (O_2) and hydrogen peroxide (H_2O_2), respectively. Finally, a number of small bacterial products, such as the phenolic glycolipid and LAM of mycobacteria, scavenge ROIs. Many of the strategies used to counteract the effects of ROIs also overlap in their effects on RNIs. A modification of lipid A renders gram-negative bacteria, including salmonellae, resistant to the effects of host antimicrobial peptides.

Intraphagosomal Survival

Inhibition of phagolysosome fusion represents a major intracellular survival strategy for a number of intracellular bacteria, including *M. tuberculosis*, *Francisella* spp., *Brucella* spp., and *L. monocytogenes* (Fig. 26.2). After engulfment, these pathogens manipulate the endocytic fate of the phagosome that contains them. This is achieved in part by manipulation of Rab GTPases, proteins required for normal endocytic trafficking, positioned in the phagosome membrane.[30] Rab GTPases associated with phagosome maturation of the pathogen-containing phagosome are Rab3, -4, -5, -9, -7, -11, and -14. These proteins are associated with different maturation stages of the phagosome and chiefly orchestrate membrane fusion events to allow delivery of vesicular protein cargo to the phagosomal compartment. The mycobacteria-containing phagosome acquires Rab5a but not the late endosomal marker Rab7a, which ultimately mediates fusion of the bacterial-containing phagosome with lysosomes that contain proteolytic enzymes active at low pH. By enabling arrest of this maturation, *M. tuberculosis* maintains its compartment at an early endosomal stage. This compartment does not acidify, partly because of a paucity of vacuolar H^+ adenosine triphosphatase (ATPase); at the same time, it exchanges molecules with the plasma membrane, such as the transferrin receptor, to access iron. Activation of macrophages with IFN-γ restores the normal maturation of the mycobacterial phagosome, resulting in a drop in mycobacterial viability. Francisellae and brucellae are engulfed by phagosomes that acquire the early endosomal markers EEA1 and Rab5a.[31] The *Francisella*-containing vacuole acquires late endosomal markers, but the pathogen escapes into the cytosol by perforating the late endosomal membrane. After a transient phagosomal stage, brucellae enter compartments enclosed by endoplasmic reticulum (ER) membranes to escape delivery to phagolysosomes.

Phenotypic Plasticity of the Infected Cell

The ability of intracellular bacteria to influence the phenotypic fate of both the cell in which it dwells and the cells within lesions that form as a result of unresolved infection is becoming increasingly

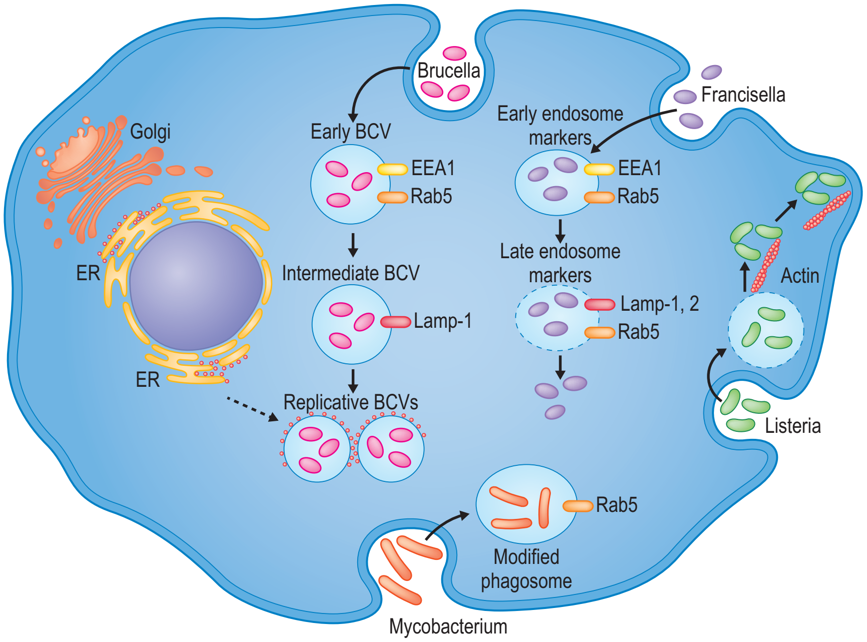

FIG 26.2 **Inhibition of Phagolysosome Fusion Represents a Major Survival Strategy for a Number of Intracellular Bacteria, Including *Mycobacterium Tuberculosis, Francisella* spp., *Brucella* spp., and *Listeria Monocytogenes.*** The mycobacteria-containing phagosome acquires Rab5 but not the late endosomal markers Lamp-1 and 2, enabling arrest of maturation of this compartment at an early endosomal stage. *Francisella* spp. and *Brucella* spp. are engulfed by phagosomes that acquire the early endosomal markers EEA1 and Rab5. The *Francisella*-containing vacuole acquires late endosomal markers but escapes into the cytosol by perforating the late endosomal membrane. A similar strategy is adopted by *L. monocytogenes.* After a transient phagosomal stage, brucellae enter compartments enclosed by endoplasmic reticulum (ER) membranes to escape delivery to phagolysosomes. BCV, Brucella-containing vacuole.

appreciated. This has already been highlighted by the tendency of *M. tuberculosis* to use its own membrane lipids to exploit host chemotactic pathways to recruit bacterial growth-permissive macrophages to the site of infection; this process subsequently allows a proliferative head-start before adaptive immunity kicks in and amplifies intracellular defences by the action of cytokines, such as IFN-γ and TNF-α. Moreover, bacterial killing must be tempered inside the granuloma to prevent destruction of host tissue. This is achieved by balancing macrophage phenotypes ranging from a phenotype highly bactericidal, termed "classically" activated, to a phenotype that is more suppressive of inflammation and is associated with wound healing and fibrosis, termed "alternatively" activated. Tipping the balance one way or the other is detrimental for the host in terms of disease.

Myeloid-derived suppressor cells (MDSCs) represent a certain stage of development of myeloid cells (both of monocytic and granulocytic lineage).[32] Although most of our knowledge stems from their suppressive role in cancer, recent evidence suggests that they play a role in control of chronic infections, such as TB.[33] They can be distinguished from canonical MPs and granulocytes by means of distinct surface markers. The granulocytic MDSCs are CD11b$^+$ LY6G^{hi} Gr1^{int}, whereas monocytic MDSCs are CD11b$^+$ LY6G^{neg} LY6C$^+$ Gr1^{hi}.

More recent findings point to host cell reprogramming resulting from intracellular infection. During intracellular infection of Schwann cells, *M. leprae* is able to downregulate genes active for the Schwann cell phenotype and upregulate genes that orchestrate differentiation to a "stem cell–like" phenotype. This stem cell–like property allows the infected cell to differentiate further to multiple mesenchymal cell states, such as skeletal cells or smooth muscle cells.[34] This ability to regress and then reprogram an infected cell phenotype could play a role in spreading infection throughout the host during leprosy.

Recently, mesenchymal stem cells (MSCs) were identified as an intracellular niche of *M. tuberculosis* in mice, and the equivalent human MSC phenotype could be readily infected *in vitro*. Because they reside in hypoxic niches and most antimycobacterial therapies are inactive in these conditions, it is feasible that MSCs could maintain the bacteria during long-term infection and could represent a protective niche from drug therapy. Dormant *M. tuberculosis* has also been detected in hematopoietic stem cells (HSCs) in mice and humans. HSCs are pluripotent, giving rise to both lymphoid and myeloid cell lineages in the blood. Clarification of the pathophysiological context of carriage of M. tuberculosis by both HSCs and MSCs is an exciting prospect.

Escape Into Cytoplasm

A successful strategy for survival inside activated macrophages is egression from the phagosome into the cytoplasm, which has been exploited by *L. monocytogenes* and the various pathogenic *Rickettsia* spp. (see Fig. 26.2).[35,36] This has the advantage of both avoiding the cellular defense mechanisms within the phagosome and providing the bacteria with a nutrient-rich environment. *L. monocytogenes* possesses several virulence factors to facilitate its escape from the phagolysosome, a pore-forming hemolysin (listeriolysin [LLO]) that acts together with a metalloproteinase, a lecithinase, and two phospholipases to efficiently promote the rupture of the phagosomal membrane and to spread to other cells. *M. tuberculosis* and *M. leprae* can also egress from the phagosome into the cytoplasm of macrophages and DCs, a behavior that is mediated by a mycobacterial protein secretion system ESX-1.[37] Bacterial virulence factors secreted by ESX-1 may also contribute to increased cell death and are not expressed by the vaccine BCG, which hence does not escape from the phagosome.

T LYMPHOCYTES AS SPECIFIC MEDIATORS OF ACQUIRED RESISTANCE

Activated macrophages act as the nonspecific executors, whereas T lymphocytes are the specific mediators of acquired resistance against intracellular bacteria. The dramatic increase in the incidence of TB and other intracellular bacterial infections in patients with AIDS illustrate the central role of T lymphocytes in protection. For instance, 15 million individuals are coinfected with HIV and *M. tuberculosis,* and HIV increases the risk of developing TB by several orders of magnitude resulting in more than 1 million TB cases annually. At the site of microbial growth, T lymphocytes not only initiate the most potent defense mechanisms available, they also focus this response to the site of encounter, thus minimizing collateral damage to the host. Although protective T-cell responses are multifactorial, they can be reduced to a few principal mechanisms (Fig. 26.3).

As previously mentioned, T cells inevitably also produce pathology through cytotoxic antimicrobial defense mechanisms. Moreover, pathogenesis of intracellular bacterial infection is highly influenced by T cells. It is therefore important that the T-cell response be tightly controlled and downregulated, when necessary. Regulatory mechanisms, including regulatory T cells (Tregs), are in place to limit immunopathology.[19]

Protective immunity involves the so-called conventional T-cell sets, CD4 αβ T cells, and CD8 αβ T cells, as well as unconventional T cells, such as γδ T cells, CD1-restricted αβ T cells, and T cells that recognize antigen in the context of other nonclassic MHC class I molecules, such as mucosal-associated invariant T (MAIT; Chapter 20) cells (see Fig. 26.3). Although these T-cell sets perform different tasks, substantial redundancy exists. Furthermore, these T-cell populations act in a coordinated way in close interaction with other leukocytes. Depending on the etiological agent and the stage of disease, the relative contribution of the different T-cell subsets to acquired resistance may vary. The conventional αβ T cells make up more than 90% and γδ T cells less than 10% of all lymphocytes in the blood and peripheral organs of humans and mice. However, γδ T cells represent a significant proportion of the intraepithelial lymphocytes in mucosal tissues, suggesting a particular role at this important port of microbial entry.

CD4 T Cells

The CD4 T-cell population can be further subdivided into distinct subsets, according to their pattern of cytokine production and expression of unique transcription factors that control patterns of gene expression (Chapter 16). At least four major subsets exist, T-helper cell-1 (Th1), Th2, Th17, and Tregs. The first two subsets were discovered over 20 years ago and have been identified in both mice and humans: Th1 cells, which overwhelmingly produce IFN-γ and IL-2, and Th2 cells, which produce IL-4, -5, and -13. The Th1 subset can also be defined on the basis of the T-bet transcription factor and the signal transducer STAT4, whereas Th2 classification is consistent with expression of the transcription factor GATA-3 and signal transducer STAT5.

Th17 cells express the retinoid orphan receptor γt (ROR-γt) transcription factor and the signal transducer STAT3. They produce the cytokines IL-17, IL-22, and granulocyte macrophage–colony-stimulating factor (GM-CSF). Cytokines of the IL-17 family are strong inducers of granulopoiesis; of proinflammatory mediators,

FIG 26.3 **T-Cell Stimulation During Infection.** (A) Recognition of bacterial antigen by T cells. Antigen originating from intracellular bacteria is presented to conventional CD4 and CD8 T cells. Unconventional T cells including γδ T cells, mucosa-associated invariant T (MAIT) cells, and CD1-restricted T cells are also activated. Human γδ T cells recognize small molecules containing pyrophosphate residues; MAIT cells recognize bacterial metabolites, such as vitamin B_2 derivatives, in the context of major histocompatibility complex (MHC)–related (MR) gene products; CD1-restricted T cells recognize glycolipids in the context of CD1 molecules. (B) CD4 T cells can be subdivided into different T helper (Th) cells according to their cytokine expression pattern. Th1 cells are critical for protection against intracellular bacteria. They typically produce interferon-γ(IFN-γ), tumor necrosis factor-α(TNF-α), lymphotoxin (LT), interleukin (IL)-2, and granulocyte macrophage–colony-stimulating factor (GM-CSF). Th2 cells stimulate humoral immune responses via secretion of IL-4 and IL-5. Other cytokines produced by Th2 cells include IL-13 and IL-25. Th17 cells produce IL-6, -17, -21, and -22, which probably contribute to early protection. Regulatory T cells (Tregs) produce transforming growth factor β(TGF-β) and IL-10, which suppress immune responses. ICOS, inducible costimulatory molecule; PD-1, programmed death 1; PD-L, program death ligand; RA, retinoic acid; TCR, T-cell receptor. See Chapters 9 and 12 for details. such as IL-6; and of the chemokines CXCL1, CXCL8, and CXCL6, which attract neutrophilic and eosinophilic granulocytes and prolong their survival.[38] Th17 cells, too, have limited importance for protection in murine models against primary infection with mycobacteria, salmonellae, and listeriae. However, Th17 cells can drive more rapid Th1 responses against pulmonary TB in mice after vaccination, resulting in enhanced protection. IL-17 is also required for optimally protective Th1 responses during murine *F. tularensis* infection.[39]

Despite the convenience of defining T-cell populations in terms of subsets, recent evidence suggests considerable plasticity in cytokine production by T cells. This was first suggested by demonstration that all subsets could produce IL-10, which regulates potency of T-cell responses to limit host collateral damage during immune responses. IL-10 expression might be an intrinsic control mechanism common to all T cells. However, reduction in T-cell potency also favors chronic intracellular bacterial infection. T-cell subsets may acquire the ability to produce additional cytokines by expression of additional transcription factors or by remodeling chromatin structure.[40] Future research will redefine T-cell behavior during intracellular bacterial infection.

CD8 T Cells

Infection of mice deficient in specific T-cell subsets has conclusively demonstrated a role for CD8 T cells during listeriosis and TB.[41] Furthermore, CD8 effector T cells have been identified in granulomas of patients with tuberculoid leprosy with low numbers of bacteria. The cytolytic potential of these T cells can serve two roles in infection with intracellular bacteria, namely, target cell killing or lysis of cells that are unable to control the infection, thus releasing the bacteria for phagocytosis by more activated cells. In humans, CD8 T cell–mediated killing is cell contact dependent and based on production of perforin, granzymes, and granulysin.[42] Finally, CD8 T cells are also a potent source of IFN-γ and TNF-α, thus contributing to direct activation of infected macrophages to enhance protective mechanisms (see Fig. 26.3).

CD8 T cells recognize antigenic peptides in the context of MHC class I gene products, which are responsible for presentation of antigens residing in the cytosol. Initially, therefore, it was mysterious how CD8 T cells were stimulated by intracellular bacteria, which were thought to have a uniquely restricted phagosomal residence. However, with the knowledge that many intracellular bacteria egress into the cytoplasm, one major mechanism for MHC class I processing became obvious: proteins secreted by bacteria in the cytoplasm undergo antigen processing and presentation similarly to newly synthesized proteins of viral or host origin.[35] Yet, alternative contact points for MHC class I molecules and bacterial peptides exist. Cross-presentation by noninfected antigen-presenting cells (APCs) of antigens engulfed within apoptotic blebs from infected cells represents a critical pathway to induce CD8 T cells by phagosomal bacteria (see below). One major advantage of CD8 T cells over CD4 T cells is their recognition of antigen bound by MHC class I gene products, which are expressed by almost all host cells. Thus CD8 T cells recognize professional and nonprofessional phagocytes equally well.

Unconventional T Cells

The relevance of the γδ T cells to antibacterial immunity is incompletely understood. Several studies indicate that γδ T cells are rapid producers of IL-17 at sites of bacterial implantation. Transient participation of γδ T cells in protection and a unique requirement for γδ T cells in granuloma formation have been described for murine listeriosis and TB. Murine γδ T cells appear to recognize peptides presented by nonpolymorphic MHC class I molecules, whereas human γδ T cells respond to nonpeptidic phosphorylated metabolites, notably from the isoprenoid pathway of bacterial and host origin.[43]

MAIT cells are primarily localized at mucosal sites, and current evidence suggests that they play a role in control of bacterial infections in mucosal tissues, such as lung (*M. tuberculosis*) and gut (gram-negative bacteria) tissues. Antigenic ligands include derivatives of vitamin B_2 (riboflavin), produced by many intracellular bacteria, including salmonellae and mycobacteria.[44-46]

CD1 comprises a group of nonpolymorphic MHC-related molecules that can present glycolipid antigens to unconventional T cells. In humans, group 1 CD1-restricted T cells respond to a variety of microbial glycolipids, including LAM, PIMs, mycolic acids, sulfatides, sulfoglycolipids, and lipopeptides.[47] Group I CD1 molecules are absent in mice. The group II CD1 molecule CD1d is present in both humans and mice and controls development of natural killer T cells (NKT cells) that express the NK cell marker NK1.1. Upon antigen activation, these T cells rapidly produce cytokines and are capable of producing both IL-4 and IFN-γ. Bacterial antigens recognized by NKT cells, PIMs from mycobacteria, and glycosphingolipids from *Ehrlichia* and *Sphingomonas* spp. have been identified. NKT cells also respond to host endogenous lysosomal lipids loaded onto CD1d.[48]

In summary, unconventional T cells often recognize nonpeptidic ligands of bacterial origin, emphasizing that they play a particular role in immunity against bacteria, including intracellular bacteria. Because of the highly skewed T cell receptor, these T cells are specific for a limited variety of bacterial ligands. Because of their less demanding antigen recognition and activation requirements, unconventional T cells may fill a gap between prompt innate resistance and the delayed conventional T-cell response.

T-Cell Memory and Regulation of Immune Responses

Long-term protective immunity against infectious agents relies on immune memory, which forms the basis for the success of all vaccines. Memory T cells can be divided into central memory T (T_{CM}) cells and effector memory T (T_{EM}) cells, based on differential surface phenotypic and tissue migration patterns.[49] T_{EM} cells accumulate in peripheral tissues where they express effector functions, whereas T_{CM} cells persist in lymph nodes, where they rapidly develop into T_{EM} cells after secondary antigen encounter. The tissue-resident memory T (T_{RM}) cells are localized to mucosal sites, where they provide efficient protection against invading pathogens.[50] Although it is generally accepted that memory T cells can survive in the absence of persistent antigen, little is known about the induction and maintenance of long-lasting T-cell memory in chronic infections with intracellular bacteria.[51]

B Cells

Although antibodies produced by B cells appear to play a minor biological role in infections with intracellular bacteria, many facultative intracellular bacteria spend some time outside their host cells, where they are accessible to antibodies.[52] Thus antibodies contribute to protection against salmonellae. Besides antibody production, B cells are potent APCs for soluble antigens, including lipids presented by CD1c, and secrete many cytokines otherwise associated with T cells, DCs, and macrophages. B-cell signaling via MyD88 during *S. typhimurium* infection has been associated with B-cell production of IL-10, and mice with B-cell-specific deficiency in MyD88 were more resistant to infection demonstrating that, like T cells, B cells can perform regulatory functions.[53]

KEY CONCEPTS

How Might a Vaccine Work?

- Activation of innate immunity for instruction of appropriate acquired immune responses (PRRs)
- Activation of the appropriate array of T-cell populations
- T-cell secretion of appropriate cytokine combination
- Efficient development of T-cell memory
- Efficient activation of antibacterial effector mechanisms
- Best case scenario: sterile pathogen eradication
- Second best case scenario: driving the infection "deeper" into latency, thus efficiently preventing reactivation of disease

Regulatory T Cells

Intracellular bacteria can cause detrimental inflammation and tissue damage, for example, as a result of IFN-γ- and TNF-α-mediated Th1 responses. Under normal circumstances, control mechanisms are in place to limit immunopathology. Such countermeasures are elicited as part of the ongoing immune response during infection. The main cytokines that limit inflammation and control IFN-γ production are IL-10 and TGF-β. Although macrophages and DCs produce these cytokines, their main producers are Tregs, which are the prime cells involved in immune regulation. Natural Tregs are responsive to IL-2 because of high constitutive CD25 expression and are characterized by expression of the transcription factor FOXP3.[54] Expansion of Tregs appears to be both antigen dependent and antigen independent. In addition, Tregs selectively express TLRs and can be activated, for example, by LPS and possibly other TLR ligands. This makes their immediate activation during bacterial infection a probable scenario. Although Tregs limit CD8 T-cell responses in experimental listeriosis, their general role in infections with intracellular bacteria has not been fully elucidated. Suppression of T-cell responses and anergy have been clinically documented for TB and leprosy. Although Treg functions can limit detrimental T-cell responses and immunopathology, they can also prevent elimination of bacteria, and hence are likely a key factor in promoting the persistent chronic state of infection with intracellular bacteria.

CONCLUDING REMARKS

ON THE HORIZON

- Design of biomarkers to discriminate latent infection from active tuberculosis (TB) and to predict risk of progression to active TB
- Development and clinical testing of new drugs for multidrug-resistant/extensively drug-resistant (MDR/XDR) TB and dormant *M. tuberculosis*
- Developing host-directed therapy (HDT) in adjunct to conventional drugs, notably for highly drug-resistant pathogens
- Development and clinical testing of new vaccines that protect against pulmonary TB in adults
- Reduction of the unequal burden of TB in developing and industrialized countries by public health measures, education, and socioeconomic advances

Our deepening understanding of the molecular events governing intracellular bacterial infections is allowing development of novel therapeutic and preventive approaches. The need for such interventions is becoming all the more pronounced in the face of increasing levels of antibiotic resistance of bacteria, such as *M. tuberculosis,* which render canonical drugs that specifically target bacterial molecular processes ineffective. A new approach, termed *host-directed therapy* (HDT) aims to develop new drugs or repurpose previously approved ones that are directed at host molecular processes.[55] Such approaches include monoclonal antibodies (mAbs) to neutralize cytokines, such as TNF-α or IL-6, to abrogate tissue destructive inflammation, repurposed use of licensed drugs, such as ibuprofen and verapamil, to modulate inflammation and enhance antibiotic effectiveness, respectively, and use of immunostimulatory natural molecules, such as vitamin D_3 to enhance bacterial killing by xenophagy. These approaches range from preclinical and early-stage clinical development to late-stage clinical development and offer promise to shorten the traditional duration of therapy.

It is being increasingly recognized that the interaction between intracellular bacteria and the immune system is not of the "all or nothing" type but is instead a "continuous struggle." This realization has far-reaching implications for preventive and therapeutic strategies against intracellular bacterial infections. First, vaccination against intracellular bacteria has not yet been effected satisfactorily because of the involvement of several distinct T-cell subsets with different modes of stimulation and activity profiles. Second, chemotherapy has frequently proven to be suboptimal for the sterile eradication of bacteria hidden in cellular niches. A better understanding of the complex crosstalk between cytokines, T lymphocytes, macrophages, and infected host cells will no doubt directly promote the development of improved control measures.[55]

MULTIPLE-CHOICE QUESTIONS

1. Which disease caused by intracellular bacterial infection results in the HIGHEST level of global mortality?
   A. Typhoid
   B. Tuberculosis
   C. Legionnaires' disease
2. Which host cytokine molecule is the MOST important in augmenting host cell defense mechanisms against intracellular bacteria?
   A. Interleukin (IL)-4
   B. IL-17
   C. Interferon (IFN)-γ
3. Which of these host cell processes is **NOT** harnessed for protection against intracellular bacterial infection?
   A. Autophagy
   B. Necrosis
   C. Apoptosis
4. Which bacterial-derived ligand is presented to T cells via major histocompatibility complex (MHC) class I?
   A. Lipopolysaccharide
   B. Polypeptide
   C. RNA

Host Defenses to Extracellular Bacteria

Marcos C. Schechter, Sarah W. Satola, David S. Stephens

The human host has developed protective mechanisms to interact with the multitude of bacterial species encountered in nature. These host defenses include nonspecific mechanisms of clearance, as well as innate and specific adaptive immune responses. Partly because of these mechanisms, the vast majority of bacterial species do not cause human disease. Many bacterial species have established symbiotic or commensal relationships with the human host and colonize skin and mucosal surfaces. These commensals are generally of low virulence except in individuals whose host defenses are compromised. Given the diversity of the microbial world, a relatively few pathogenic bacterial species or subpopulations of those species have evolved virulence factors or strategies that can overcome or circumvent intact human host defense mechanisms to cause localized or systemic disease.

Important bacterial pathogens of clinical importance reside mostly extracellularly (Table 27.1). Examples are bacterial pathogens typically labeled *extracellular*, such as *Streptococcus pneumoniae*, *Streptococcus pyogenes*, *Haemophilus influenzae*, *Neisseria meningitidis*, *Neisseria gonorrhoeae*, and *Bordetella pertussis*, which are transmitted from one individual to another by close contact. Other "extracellular" bacterial pathogens, such as *Clostridium* spp. *Vibrio cholerae*, *Shigella dysenteriae*, enteropathogenic *Escherichia coli*, and *Bacillus anthracis*, are transmitted through food, water, animal, or other environmental contact. *Staphylococcus aureus* is an important extracellular pathogen for humans and can be acquired from other humans, from animals, or through environmental contact. Acquisition of these pathogenic bacteria may be transient, result in variable intervals of colonization, or rapidly cause localized or systemic disease.

Extracellular bacterial pathogens can produce acute inflammatory and purulent infectious diseases, such as meningitis, septicemia, pneumonia, urethritis, pharyngitis, inflammatory diarrhea, cellulitis, and abscesses and/or produce disease by the release of toxins. Disease associated with some extracellular bacteria (*e.g., Helicobacter pylori*) results from chronic colonization. Susceptibility to extracellular bacterial pathogens is enhanced by hereditary, acquired, or age-related defects in innate or adaptive host defenses. Resistance to extracellular bacterial pathogens or their toxins can be accentuated by chemoprophylaxis, by vaccines, and by other immune modulation processes (*e.g.,* passive immune globulin administration). Caution is urged in the interpretation of the term "extracellular." The classification of bacteria as "extracellular" and "intracellular" is primarily based on observations *in vitro* and has been challenged by some authors, as some "extracellular" bacterial species invade host cells as a part of their normal lifecycle and during steps in the disease process (*e.g., S. aureus, S. pneumoniae, S. pyogenes, N. meningitidis*).[1] Conversely, bacteria typically classified as "intracellular" can have an extracellular component to their lifecycle (*e.g., Mycobacterium tuberculosis* in cavitary lesions).

Host defense mechanisms against extracellular bacteria are a continuum. The innate and adaptive immune systems cooperate to protect the host from extracellular bacterial infections. The innate immune system senses bacteria through pattern recognition receptors (PRRs; Chapter 3). These receptors activate antimicrobial defenses and stimulate the adaptive response, all while balancing excessive immune and inflammatory responses with the need to protect against the infecting pathogen.[2]

CLINICAL PEARLS

Distinguishing Clinical Characteristics of Infections With Extracellular Bacteria

- Sterilizing immunity
- Colonization of mucosal surfaces often precedes disease
- Causes of pyogenic infections
- T-helper (Th)17 response critical in generating a neutrophilic response
- Antibodies are protective for some of the major pathogens
- Effective vaccines available for many of the major pathogens

CLEARANCE AND NONSPECIFIC HOST DEFENSES AT MUCOSAL EPITHELIAL SURFACES

Bacteria first encounter a physical barrier, which comprises skin, mucus and mucosal surfaces, and the normal microbiota, as well as nonspecific factors, such as nutrient limitation (*e.g.,* iron), and antimicrobial proteins or peptides. Intact skin and mucosal surfaces provide complex chemical and biological obstacles to extracellular bacteria and are an important line of defense preventing the invasion of these pathogens and their products.[3] Humans commonly carry extracellular pathogens asymptomatically on skin and at respiratory and gastrointestinal (GI) mucosal surfaces. To cause disease, pathogens breach or disrupt epithelial barriers. Damage to epithelial barriers as a result of trauma; coinfections; drugs, such as those used in chemotherapy; environmental factors, such as smoking, allergies, or low humidity; and catheterization and intubation circumvent these barriers and allow bacteria access to subcutaneous tissues, blood vessels, and other normally sterile sites. Additionally, acquired and genetic diseases affecting epithelial barriers are also linked to increase in infections.

The human epithelium has evolved to prevent colonization and invasion by pathogenic organisms.[3] Skin is a relatively dry, acidic (pH 5–6) barrier that contains growth-inhibiting fatty acids and antimicrobial peptides (AMPs) (see below), characteristics that

TABLE 27.1 Examples of Clinically Relevant Pathogenic Extracellular Bacteria

Species	Examples of Human Disease	Selected Mechanisms of Pathogenesis	Special Features Key to Host Infection	Examples of Susceptible Populations/Risk Factors
Staphylococcus aureus	Cellulitis, abscesses, bacteremia, endocarditis, toxic shock syndrome, osteomyelitis, pneumonia, wound infections	Protein A: promotes fibronectin binding PVL: cytotoxic α-toxin: membrane damage TSST-1: superantigen	Asymptomatic colonization, resistant to dehydration	Injection drug users, patients on hemodialysis, defects on Th17 response (Job's syndrome), Surgical procedures and skin trauma
Streptococcus pneumoniae (*Pneumococcus*)	Pneumonia, otitis media, meningitis	Capsule: prevents phagocytosis, antigenic variation Pneumolysin: cytotoxic PspA & C: inhibition of complement Neuraminidase, hyaluronidase: spread and colonization IgA_1 protease	Asymptomatic colonization, readily acquires new genes through transformation	Smokers, cerebrospinal fluid leak, asplenia, hypogammaglobulinemia, human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS), unvaccinated children
Streptococcus pyogenes (group A *Streptococcus*)	Pharyngitis, cellulitis, erysipelas, toxic shock syndrome, necrotizing fasciitis, scarlet fever, rheumatic fever	Hyaluronic acid capsule, M-protein: prevents phagocytosis Streptolysin O & S: cytotoxic Streptococcal pyrogenic exotoxins C5a peptidase	High diversity of M-proteins, molecular mimicry of human antigens	School-age children, crowded-conditions (*e.g.,* military barracks), injury to lymphatic system (*e.g.,* surgical harvest of saphenous vein)
Streptococcus agalactiae (group B *Streptococcus*)	Neonatal sepsis, pneumonia and meningitis, perinatal infections, bacteremia	FbsA: fibrinogen receptor, promotes adherence Capsule β-hemolysin C5a peptidase β protein: downregulates complement	Asymptomatic colonization, acquisition by infants during birth	Neonates and infants (immunity dependent on passive transfer of maternal antibodies), diabetes mellitus
Neisseria meningitidis (*Meningococcus*)	Meningitis, bacteremia (purpura fulminans)	Capsular polysaccharide: promotes adherence and prevents phagocytosis Type IV pili: promote attachment to host cells LOS: analogues to LPS, activates TLR4 pathway IgA_1 protease fHbp: downregulates the host alternative complement pathway	Molecular mimicry of human antigens, phase and antigenic variation, asymptomatic carriage	Terminal complement deficiencies, hypogammaglobulinemia
Neisseria gonorrhoeae (*Gonococcus*)	Urogenital infections, disseminated gonococcal infection, pharyngitis	Type IV pili: promote attachment to host cells Opa protein adhesion IgA_1 protease LOS: analogs to LPS, activates TLR4 pathway	Phase and antigenic variation, molecular mimicry of human antigens	Terminal complement deficiencies, women during menstrual period (increases risk of dissemination)
Escherichia coli	Urinary tract infections, gastroenteritis, sepsis, neonatal meningitis	Capsular polysaccharide Tissue specific fimbriae Heat-labile enterotoxins: increases intestinal chloride secretion LPS: activation of TLR4	Antigenic heterogeneity of LPS and capsule	Bladder instrumentation, pregnancy
Pseudomonas aeruginosa	Ventilator-associated pneumonia, bronchiectasis	Pili and flagella: attachment to the host and formation of biofilms LPS Exotoxin A Lipases, lecithinases, elastase	Considerable adaptability to changes in environment, large genome size, biofilms	Orotracheal intubation, cystic fibrosis
Clostridium difficile	Colitis	Toxin B: cytotoxic Flagella	Endospore formation, asymptomatic carriage	Antibiotics and other disruptions of the microbiota
Haemophilus influenzae	Otitis media, pneumonia, epiglottitis, bacteremia, meningitis	LPS with phosphorylcholine Pili: adherence Capsule High-molecular weight adhesins IgA_1 protease	Phase variation of pili, asymptomatic carriage	Unvaccinated children, immunocompromised, sickle cell disease, smoking
Helicobacter pylori	Peptic ulcer disease	Urease: colonization of gastric mucosa Flagella: motile in gastric mucus CagA; bacteria-derived carcinogen	Polymorphism of CagA	Crowded living conditions, unreliable source of clean water, living with someone who has *H. pylori*
Bordetella pertussis	Whopping cough (children), chronic cough (adults)	Pertussis toxin: inhibits neutrophils, macrophages, lymphocytes Pertactin & filamentous hemagglutinin; mediates attachment	Antigenic variation of adhesins	Nonvaccinated adults and children, infants who have not completed vaccine series, adults and adolescents whose immunity has diminished

TSST-1, toxic shock syndrome toxin 1; Psp, pneumococcal surface protein; LOS, lipooligosaccharide; fHbp, Factor H-binding protein; LPS, lipopolysaccharide; CapA, cytotoxin-associated gene A; Ig, immunoglobulin; TLR, Toll-like receptor; PVL, Panton-Valentine leukocidin.

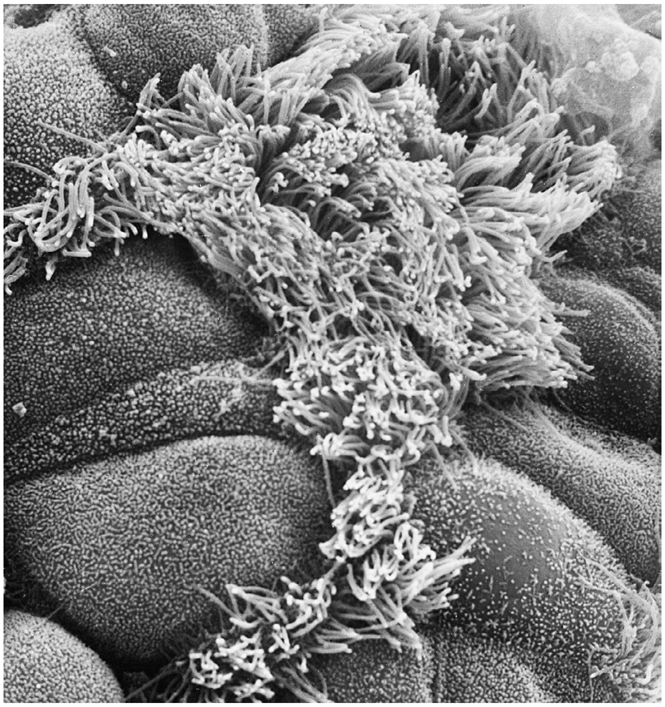

FIG 27.1 **Mucociliary Host Defense.** Scanning electron micrograph of human upper respiratory mucosa showing the ciliated and nonciliated epithelial surface (×16000).[41]

are detrimental to many bacteria. The constant desquamation of stratified epithelial surface of skin helps in the removal of microorganisms.[4] Nevertheless, a complex skin microbiome that can include bacterial pathogens has been identified, and this differs remarkably, depending on location in the body. Disruption of these physical barriers can augment pathogen tissue colonization and invasion. Infections by *S. aureus* and *S. pyogenes*, bacteria that can colonize skin, are often preceded by skin damage. Repeated trauma to skin (*e.g.*, dialysis and intravenous drug use) also enhances skin colonization with pathogens, including that by *S. aureus*.

Mucosal surfaces have additional nonspecific antibacterial defenses. The mucociliary blanket of the respiratory tract (Fig. 27.1) and the female urogenital tract (fallopian tube) move bacteria away from epithelial surfaces, as does the flushing of the urinary tract with urine, intestinal peristalsis, and the bathing of the conjunctiva with tears. Lysozyme is found in most mucosal secretions and lyses bacterial cell walls by splitting muramic acid β(1–4)-*N*-acetyl-glucosamine linkages. The acid pH of the stomach, intestinal peristalsis, and the antibacterial effect of proteolytic enzymes present in intestinal secretions are important GI tract host defenses against many pathogenic bacteria. The GI mucosa has a layer of mucus that acts as a physical shield to bacteria. Mucus is rich in mucin, glycoproteins that limit pathogen binding to other host molecules necessary for mucosal adhesion. Additionally, the mucus layer may function more than as a physical barrier by acting as a diffusion barrier to concentrate antimicrobial proteins at the appropriate epithelial cell surface. The glycocalyx, an extracellular layer of the apical surface of mucosal cells composed of carbohydrates, also protects cells against bacterial attachment.

Bacterial attachment and colonization of mucosal surfaces can be inhibited by bacterial binding to human cellular antigens present in secretions, such as ABO blood group antigens. Cell adhesion and extracellular matrix molecules, such as fibronectin and proteoglycans, can also inhibit or enhance bacterial binding to epithelial surfaces. The Tamm-Horsfall glycoprotein, found in urine, can bind avidly to a variety of bacteria and facilitate clearance. Proteins, such as lactoferrin (Lf), present at mucosal surfaces, bind iron, an important requirement for bacterial growth. This action may reduce microbial proliferation, but some mucosal pathogens bind Lf and remove iron from the molecule for growth.

Normal Microbiota as Host Defense

The human microbiome is now recognized as a major host defense against bacterial pathogens by providing “colonization resistance,” maintaining a balance of commensals to pathogens, and by priming the immune system (Chapter 14).[5] Altering or disrupting the normal microbiota by antibiotics facilitates the expansion of enteric pathogens as *Clostridium difficile* and *Salmonella typhimurium* or selection of antibiotic-resistant members of the microbiome. Similarly, changes in human physiology, for example, exposure of skin to elevated temperatures and humidity, chronic stress, host immune suppression, or active behavioral changes, such as smoking, can cause a commensal-to-pathogen switch. Recent studies have demonstrated that certain resident microbiota can resist pathogen colonization and infection. For example, matched volunteers were inoculated with *Haemophilus ducreyi* into the arms, and the subsequent infection either resolved or resulted in formation of abscesses; characterization of the skin microbiome before, during, and after the experimental inoculation showed that the microbiomes of those with pustule formation and of those with resolved infection were distinct and influenced the course of the *H. ducreyi* infection.[6]

The interaction of the microbiome with the immune system is also important for defense against extracellular pathogens. Normal microbiota facilitate a high level of priming of the immune system by maintaining high levels of major histocompatibility complex (MHC) class II molecule expression on macrophages and other antigen-presenting cells (APCs). PRRs (see below) are traditionally known to recognize microbial molecules during infection; however, ligands for PRRs are abundantly produced by the resident microbiota during normal colonization. The integrity of the intestinal epithelial layer is dependent on activation of Toll-like receptors (TLRs; see below) by normal microbiota.[4] Stimulation of TLR-5 has been shown to increase resistance to *E. faecium* infection in a murine model. Activation of nucleotide oligomerization domain 1 (NOD1) receptors by gut resident microbiota is necessary for priming of the innate immune system. Additionally, resident microbiota produce such factors as bacteriocins, lantibiotics, and phenol-soluble modulin (PSM), which function in a similar manner to that of host-derived antimicrobial proteins and peptides (APPs; see below), suggesting an important host defense strategy against pathogen colonization.[7] Importantly, members of the resident microbiota can cause disease, particularly with loss of epithelial integrity and translocation to a different host tissue.

Antimicrobial Peptides and Antimicrobial Proteins

Pathogens colonizing or invading epithelial surfaces are confronted with APPs, which can be produced both by the host and the microbiota (Table 27.2).[7] In addition to pathogen killing, APPs control host physiological functions, such as inflammation, angiogenesis, and wound healing. They also limit pathogen colonization and shape the composition of the host microbiome

TABLE 27.2 Antimicrobial Proteins (AMPs) Against Extracellular Bacteria

AMP	Tissue/Cell Sources	Mechanism of Action	Target Organisms
α-defensins	Small intestines, Paneth cells	Membrane disruption; inhibits complement activation; chemoattracts dendritic cells	Gram-positive bacteria Gram-negative bacteria
β-defensins	Large intestines, skin, respiratory tract epithelial cells	Membrane disruption; lipid II binding	Gram-positive bacteria Gram-negative bacteria
Cathelicidin (LL37)	Large intestine, skin, lung, urogenital tract	Membrane disruption	Gram-positive bacteria Gram-negative bacteria
RNases	Skin, intestine, respiratory epithelia, placenta	Unknown	Gram-positive bacteria Gram-negative bacteria
Psoriasin (S100A7)	Skin, urogenital tract	Unknown	*Escherichia coli*
Calprotectin (S100A8-A9)	Abscesses/neutrophils	Metal Chelation	*Staphylococcus aureus*
C-type lectins	Small intestines	Peptidoglycan recognition	Gram-positive bacteria
Bactericidal/permeability-increasing protein (BPI)	Neutrophils, epithelial cells	Neutralizes lipopolysaccharide	Gram-negative bacteria
Lysozyme	Skin, body fluids, tears, intestinal Paneth cells	Degrades peptidoglycan	Gram-positive bacteria Some gram-negative bacteria activity
Dermcidin	Sweat glands	Membrane disruption	Gram-positive bacteria Gram-negative bacteria
Peptidoglycan recognition proteins	Liver, intestines, skin, neutrophils	Activates bacterial two-component systems; targets peptidoglycan	Especially active against gram-positive bacteria Gram-negative bacteria
Phospholipase A2	Tears, intestines	Hydrolysis of bacterial phospholipids	Gram-positive bacteria

TABLE 27.3 Immune Microbial Pattern Recognition Molecules

Toll-like receptors (TLRs)
Nucleotide-binding oligomerization domain (NOD), caterpillar proteins, peptidoglycan recognition proteins (PGRPs)
RNA helicases/PkR

C- and S-lectins: mannose-binding lectin, L-ficolin

and are both constitutively present and inducible by infection and injury.[7] Humans produce two main classes of APPs: defensins and cathelicidins. Defensins, for example, are expressed in skin, intestines, and the respiratory tract and have activity against gram-positive and gram-negative bacteria. Interestingly, APPs expression can be altered by epithelial injury. Keratinocytes of inflamed psoriatic lesions produce increased levels of certain APPs, and patients with such lesions rarely have secondary bacterial infections. In contrast, keratinocytes from patients with atopic dermatitis have dampened APP production in response to inflammation, and colonization and superinfections of the skin by *S. aureus* are common. Not surprisingly, successful pathogens have developed several mechanisms to counteract APPs. Gonococci, for example, counteract APPs with efflux pumps.

RECOGNITION OF EXTRACELLULAR BACTERIA AND ACTIVATION OF THE IMMUNE SYSTEM

Immune pattern recognition molecules (Table 27.3) are a major arm of the innate immune system and are released or expressed by a range of host cells, including lymphocytes, macrophages, or tissue histiocytes, dendritic cells (DCs), polymorphonuclear leukocytes or neutrophils (PMNs), and epithelial cells. The discovery and characterization of specific pattern recognition molecules (see below) has revolutionized our understanding of the initial specific events occurring between microbes and human cells. The identification and function of these molecules is rapidly expanding and include TLRs, NOD and caterpillar proteins, RNA helicases, complement proteins, antimicrobial peptides, collectins and surfactants, C-lectins, and S-lectins, such as mannose-binding lectin and L-ficolin.

Pattern Recognition Receptors

Innate immune recognition relies on the detection of unique molecular structures found on microorganisms by host PRRs.[8,9] TLRs and NOD-like receptors (NLRs) are the best studied PRRs (Table 27.4). TLRs (TLR1–11) (Chapter 3) are found on macrophages, neutrophils, and other host cells. These receptors recognize a variety of microbial ligands or pathogen-associated molecular patterns (PAMPs), including lipoproteins, lipopolysaccharide (LPS), flagellin, and nucleic acids produced by gram-negative and/or gram-positive bacteria. Alterations (polymorphisms) in TLRs (*e.g.,* TLR4) and other pattern recognition molecules are associated with susceptibility or severity of specific infections (*e.g.,* sepsis).[10] TLR expression can be regulated by type I interferons (IFNs) and by microRNAs (miRNAs), and the dysregulation of TLRs can be involved in acute and chronic inflammatory diseases and cancer.[11]

The NLRs are a family of intracellular receptors, some of which function as PRRs.[8] NOD1 and NOD2 are well characterized as PRRs to extracellular pathogens, such as *S. flexneri.* Importantly, in concert with TLR signaling, NLR can respond to a variety of PAMPs by forming the inflammasome complex. Inflammasome activation generates interleukin-18 (IL-18) and the active form of IL-1, an important step in the immune response to many bacteria. In addition to PAMPs, danger-associated molecular patterns (DAMPs), typically associated with activation of the innate immune system upon injury by noninfectious mechanisms, can be released both by the host and bacteria and result in amplification of the inflammatory response.

TABLE 27.4 Pattern Recognition Receptors (PRRs) Recognize Pathogen-Associated Molecular Patterns (PAMPs) From Various Bacteria

PRRs	PAMPs	Microbes
Toll-like receptor (TLR)2/1	Triacyl lipoproteins	Bacteria
TLR2/6	Diacyl lipoproteins	Mycoplasma
	Lipoteichoic acid	Gram-positive bacteria
TLR2	Peptidoglycan	Gram-positive bacteria
	Porins	Bacteria (*Neisseria*)
TLR4	Lipopolysaccharide (LPS)	Gram-negative bacteria
TLR5	Flagellin	Flagellated bacteria (*Helicobacter pylori, Salmonella*)
TLR7/8	RNA	Group B *Streptococcus*
TLR9	CpG-DNA	Bacteria (*Salmonella*)
	DNA	Bacteria (*Staphylococcus* at low MOI)
TLR11	Not determined	Uropathogenic bacteria
Nucleotide-binding oligomerization domain (NOD)1	Meso-diaminopimelic acid	*H. pylori, Bacillus* spp., *Campylobacter jejuni, Pseudomonas aeruginosa*
NOD2	Muramyl dipeptide (MDP)	*Streptococcus pneumoniae, Staphylococcus aureus, Salmonella typhimurium*
NOD-like receptor (NLR) P3	Whole pathogens	*S. aureus*
	Toxins, LPS, MDP, and RNA	Bacteria
NLRP1	MDP	Bacteria
NLRP1b	Microbial toxin	*Bacillus anthracis*
NLRC4	Flagellin	*P. aeruginosa*

MOI, multiplicity of infection.

Complement

Complement, a series of more than 20 proteins, is activated by microbial surfaces (alternative complement [AP] cascade) or via antibody or by the mannose-binding lectin system (Chapter 21). Complement activation leads to microbial lysis and the release of opsonins and chemoattractant molecules for phagocytic cells.[13] The classical complement pathway (CP) can be initiated either by antibody binding to cell surface epitopes or by antibody-independent autocatalytic activation of C1 to form C1q. Initiation of the APs by bacterial products or mannose-binding protein leads to the direct deposition of the C3b complex on the bacterial surface. Complement activation results in generation of opsonins (as C3b), anaphylatoxins (as C3a), and activation of the late components of the complement pathway, which results in the formation of a membrane attack complex (MAC). Gram-positive extracellular pathogens resist the bacteriolytic action of the MAC as a result of a thick peptidoglycan layer, which impedes the insertion of the MAC C5b-9 complex. Gram-negative bacteria can resist the MAC through structural alterations in their LPS (the possession of O antigen keeps the MAC at a distance from the bacterial surface) or by masking or deleting the epitope(s) responsible for binding bactericidal antibody.

Dendritic Cells

DCs sample live bacteria at the mucosal surface, traffic to mucosal lymphoid tissue, and induce B cells to produce bacteria-specific immunoglobulins.[4] In most tissues, DCs are at low level of activation and are immature, but upon activation, they take up and process antigen. DCs are rich in PRRs (*e.g.,* TLRs), and microbe–PRR interaction has a key role in shaping the T-cell response.[14] For example, TLR5 stimulation by bacterial flagellin can induce a Th17 response and B-cell immunoglobulin A (IgA) production. Skin contains a major supply of tissue DCs (Langerhans cells), and their involvement in combating skin and soft tissue infections must be considered along with their function and contribution to stimulating immunity during vaccination. Limited information is available regarding the role of DCs in host resistance to extracellular bacteria, but some studies have examined the interaction between bacteria and DCs. For instance, Unkmeir et al. studied the interaction of serogroup B meningococci with DCs.[12] Infection of DCs by meningococci resulted in a significant and rapid production of proinflammatory cytokines and chemokines, including TNF-α, IL-6, and IL-8 through a lipooligosaccharide (LOS)–dependent mechanism.[12] Murine studies provide some insight into the mechanisms extracellular bacteria use to avert phagocytosis by DCs. For example, *S. suis* polysaccharide capsule reduces bacterial adhesion to the DC plasma membrane.[15] Once bacteria are internalized, they must resist degradation in the DC autophagolysosomes.

KEY CONCEPTS

Host Defenses and Immune Response at Epithelial Surfaces to Extracellular Bacteria

- Clearance and nonspecific host defenses at skin and mucosal surfaces
  - Epithelial barriers
  - Antibacterial factors (fatty acids, antimicrobial peptides, lysozyme, phospholipase A_2)
  - Mucociliary activity
  - Normal microbiota
  - Adherence blocking molecules
- Specific immune defenses at mucosal surfaces
  - Innate immune mechanism
  - Immunoglobulins
  - Phagocytosis at mucosal surfaces
- Mucosa-associated lymphoid tissue (MALT), gut-associated lymphoreticular tissue (GALT), bronchus-associated lymphoid tissue (BALT)

Macrophages

Phagocytic cells, macrophages, and PMNs are also present at mucosal surfaces (Fig. 27.2). These cells express PRRs and migrate to mucosal surfaces by chemotaxis and diapedesis between epithelial cells. Macrophages are also encountered after crossing the epithelial barrier. Specialized epithelial M cells of mucosal surfaces are key sites for antigen sampling, including viruses, and bacteria and macrophages surround these sites.[16] However, enteroinvasive pathogens, such as *Shigella*, can resist macrophages. *Shigella* induce macrophage apoptotic death by direct interaction of the bacterial protein IpaB with IL-1β-converting enzyme.

Polymorphonuclear Leukocytes

In areas of epithelial inflammation, PMNs can be recruited to mucosal and skin surfaces. PMNs are more effective in the presence of specific immune defenses, such as antibody and complement components. PMNs express PRRs and have both oxygen-dependent and oxygen-independent mechanisms of killing (Chapter 3) (Fig. 27.3). Activated neutrophils can release granule proteins with direct antibacterial action (*e.g.,* bactericidal/permeability-increasing [BPI]) or degradative activity (*e.g.,*

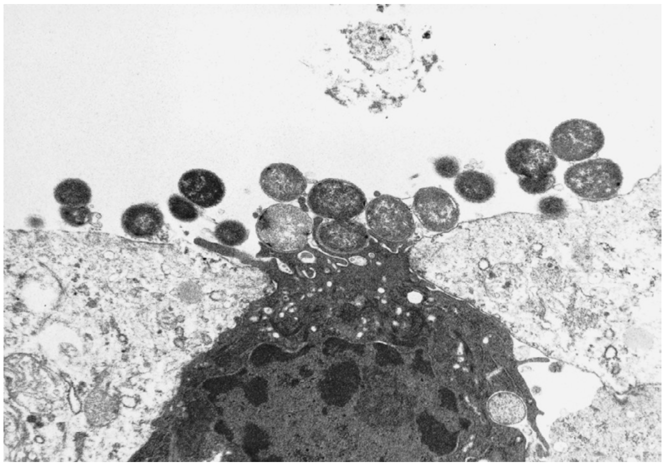

FIG 27.2 Bacterial Phagocytosis at Mucosal Surfaces. Transmission electron micrograph of phagocyte engulfing *Neisseria meningitidis* at a human respiratory epithelial mucosal surface (×19 000).[41]

FIG 27.3 Bacterial Resistance to Polymorphonuclear Leukocytes (PMNs) in the Extracellular Environment. The two principal mechanisms of bacterial resistance to PMN killing. These consist of resistance to phagocytosis as a result of bacterial surface components (*e.g.*, capsule or pili) and the action of extracellular proteins that can lyse PMNs (*e.g.*, leukocidins) or decrease chemotaxis (*e.g.*, C5a peptidase). Bacteria growing in biofilms may be more protected from PMNs than are bacteria growing in the planktonic state.

elastase) and chromatin containing the antibacterial histone H2A.[17] These released compounds work together to form extracellular fibers, termed *neutrophil extracellular traps* (NETs), which can trap and kill gram-positive and gram-negative bacteria and degrade their virulence factors as well. NETs have been observed in instances of acute inflammation (experimental dysentery and spontaneous appendicitis) and provide a mechanism for reducing bacterial spread at sites of acute infection. The importance of PMNs in host defense against extracellular pathogens can best be highlighted by the increased frequency of bacteremias and other life-threatening infections in patients with neutropenia or those individuals with neutrophil deficits (*e.g.*, chronic granulomatous disease, Chediak-Higashi syndrome, or specific granule deficiency, to name a few). Bacterial infections associated with phagocytic dysfunction are described elsewhere (Chapter 22).

Innate Lymphoid Cells

Innate lymphoid cells (ILCs), a heterogeneous group of cells of the innate immune system, have lymphoid morphology but lack the capacity for rearrangement of the antigen receptors, a cardinal feature of the cells of the adaptive immune system.[18] Conventional natural killer (NK) cells, better known for generating inflammatory cytokines and cytotoxic activity against malignant cells and cells infected by viruses, seem to have a role in the defense against bacterial pathogens. Murine study data suggest that conventional NK-cell activation by lung macrophages is protective against *S. aureus* pneumonia.[19] A subset of ILCs, known as *NK-like cells*, produces IL-22 and has been found in mucosal sites, where these ILCs appear to have a protective activity against bacterial pathogens. IL-22 derived from these cells modulates AMP expression by epithelial cells. NK-like cells have minimal cytotoxic activity and are not strong producers of IFN-γ, core characteristics of conventional NK cells.[20]

Lymphocytes

Th1 cells are characterized by IFN-γ and function to activate macrophages to phagocyte and kill pathogens. While this mechanism of pathogen elimination is primarily directed against pathogens with a predominant intracellular lifecycle, Th1 cells are relevant for typical extracellular bacteria as pneumococcus and *S. aureus*.[21] The neutrophilic response to extracellular bacteria is primarily coordinated by Th17 cells.[22] Animal models have suggested that the Th17 response is central for protection against a wide variety of gram-positive and gram-negative bacteria. For example, Th17 response has been shown to induce nasopharyngeal clearance of *Pneumococcus* in both animal models and in children. Differentiation toward the Th17 subtype appears to be favored by strong antigenic signals and broad activation of pathogen recognition receptors. IL-17 and IL-22, the signature interleukins (ILs) of the Th17 response, promote AMP secretion by epithelial cells, neutrophil migration, and epithelial integrity. The increased susceptibility of subjects with Job's syndrome to *S. aureus* infections demonstrates the importance of the Th17 response in humans.

One in five cells in the intestinal epithelium is a lymphocyte. Mucosa-associated lymphoreticular tissue (MALT) comprises intraepithelial lymphocytes (IELs), lamina propria lymphocytes, and lymphoid follicles (*e.g.*, Peyer patches) and is sometimes divided into gut-associated (GALT), bronchial-associated (respiratory tract) (BALT), and genitourinary tract lymphoid tissues (Chapter 20).[23] Lymphocytes are important for homeostatic regulation and the maintenance of immune response against microbes at mucosal surfaces, including "extracellular" bacteria. These cells express PRRs (*e.g.*, TLRs), have constitutive cytotoxic activity, secrete chemokines and cytokines important in regulation and host defense, and act in concert with mucosal epithelial cells and exocrine glands.

Innate T cells represent a heterogeneous group of cells that possess T-cell receptors (TCRs) and are restricted to MHC-like molecules.[24,25] Unlike other T cells, innate T cells gain effector capacity before exiting the thymus and therefore can respond more readily to stimuli, including infections. This has led to the idea that innate T cells provide a bridge between the innate and adaptive immune systems during infections. Invariant natural killer T (iNKT) cells, a subset of innate T cells, are restricted to the MHC-like molecule CD1d. iNKT cells can be directly activated by bacterial pathogens as a result of binding of cell wall components of gram-negative bacteria to CD1d. Interestingly, cytokines secreted by APCs that have encountered bacterial pathogens can increase iNKT-cell accumulation of self-lipid antigen for CD1d activation. Mucosa-associated invariant T (MAIT) cells are restricted by MR1, a MHC-like receptor that binds molecules derived from the microbial riboflavin synthesis pathway.[24,26] Both gram-positive and gram-negative bacteria have been shown to activate MAIT cells. Murine models of intraperitoneal inoculation of gram-negative bacteria suggest the MAIT cells are important for the early clearance of pathogens.[25,26]

Immunoglobulins

Immunoglobulins (Igs), principally secretory IgA and IgG, are present at mucosal surfaces and in mucosal secretions. Important in the generation of these immunoglobulins at mucosal surfaces is the dissemination of IgA and IgG class–committed B- and T-helper (Th) cells with specificity to an antigen encountered and processed at one mucosal site to local and distant mucosal sites. Protective mucosal antibodies against bacteria may be derived from prior colonization, vaccines, or shared cross-reactive antigens on normal flora. Mucosal Igs may neutralize bacterial toxins, facilitate phagocytosis or bactericidal activity, inhibit bacterial adherence ligands, or sterically hinder other events necessary for bacterial colonization and invasion. Many extracellular bacterial pathogens (*N. meningitidis*, *N. gonorrhoeae*, *H. influenzae*, certain streptococci) colonize and/or infect mucosal surfaces where protective IgA_1 antibodies could become available.[27] These pathogens secrete an IgA_1 protease that cleaves IgA_1, thereby inactivating the molecule. IgA_1 protease can also recognize other substrates, notably lysosomal-associated membrane protein 1 (LAMP-1), which are important in host defense. Bacterial infections associated with abnormal immunoglobulin production or function are summarized in Chapter 34.

MECHANISM OF IMMUNE EVASION AND DISEASE BY EXTRACELLULAR BACTERIA

To colonize human epithelial and mucosal surfaces, bacteria must overcome the local host defense mechanisms described above. After navigating these defenses, adhesion to host cells is usually the first important step for bacterial pathogens (Fig. 27.4). Initial attachment of bacteria to human epithelial cells is, in part, mediated by pili, fimbriae, or other bacteria ligands or adhesins, and close adherence of bacteria to the human cell-surface receptors involves the cell wall, outer membrane proteins, LPS, and other bacterial surface structures. The attachment of bacteria to human epithelial cells prevents elimination of bacteria from the host. Attachment can also induce host cell pathways leading to cytoskeletal rearrangements, such as elongation and branching of the microvilli, the accumulation of actin, and calcium efflux, which facilitates close adherence and invasion of epithelial cells by normally "extracellular" bacteria, especially at sites with fluid movement. Strains of *E. coli* that successfully colonize the bladder and cause renal infection possess pili that allow adhesion to the renal epithelium.[28,29] Type IV pili are fundamental for attachment of gonococci to the male reproductive tract and play a role on the attachment of meningococci to vascular endothelial cells.[28,30] Meningococcal pili also facilitate twitching motility and microcolony formation, which allows the penetration of mucus and provides initial attachment. The pneumococcal CbpA surface protein promotes mucosal adhesion and dissemination.[29]

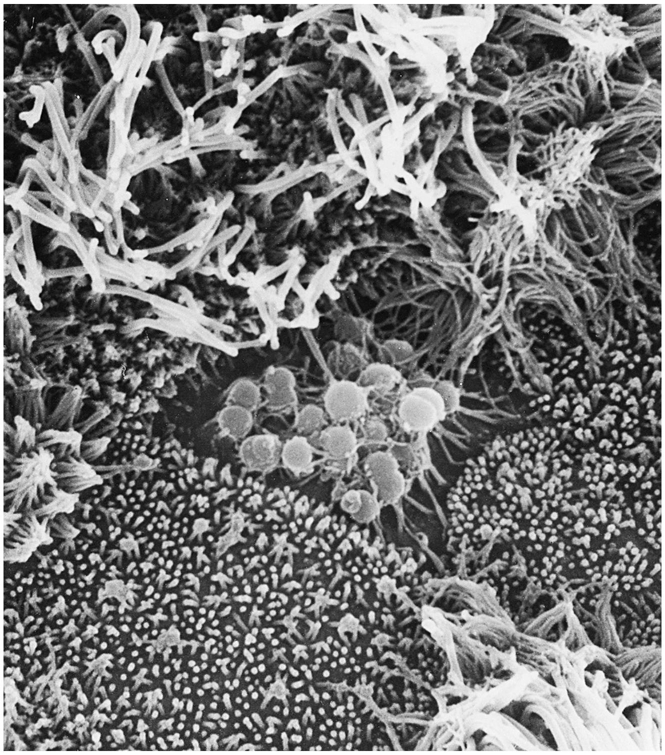

FIG 27.4 Colonization and Adherence of Extracellular Bacteria at Mucosal Surfaces. Scanning electron micrograph of *Neisseria meningitidis* adherence and microcolony formation of a human upper respiratory mucosa (×16 250).[41]

Bacteria utilize several mechanisms to avert the host immune response to bacterial surface antigens (see Table 27.1). Phase variation of adhesins is a mechanism of immune evasion common to pathogenic *Neisseria* spp. *Meningococcus*, for example, utilizes phase variation of the adhesion protein Opa and type IV pili during the process of colonization of human upper respiratory mucosal surfaces.[31] Sialylation of LPS, a potent inducer of host inflammatory response, is an example of bacterial "hiding" of surface antigens. For example, sialylation of lipooligosaccharide, a molecule analogous to LPS, in meningococci has been shown to increase resistance to CP and AP complement-mediated killing by decreasing the deposition of C3b and IgM on the cell surface, irrespective of capsular phenotype.

Many pathogenic extracellular bacteria interact with components of the complement system to induce negative regulation of the complement pathway.[29] Binding of human factor H (hfH) by meningococci factor H-binding protein (fHbp) downregulates the host AP and helps the organism to evade host innate immunity and is now included in the new serogroup B vaccines.[32] Proteolytic degradation of IgA_1 present in the urogenital and respiratory tracts is used to avert the action of the humoral system.[33] The elaboration of superoxide dismutase and catalase can reduce the efficacy of oxygen (O_2)–dependent killing of bacteria, but the high levels of O_2 radicals that accumulate in PMNs probably overcome these bacterial enzymes, as evidenced by the susceptibility of *S. aureus* to intraleukocytic killing. Several extracellular bacteria possess polysaccharide-rich capsules that resist phagocytosis. Polysaccharide capsule antigens can mimic human antigens. Antigen mimicry can lead to autoantibodies, as in the case of rheumatic fever and glomerulonephritis after *S. pyogenes* infection. Antigen mimicry can also dampen the immune response to bacterial antigens, as in the case of serogroup B *Meningococcus*. Other microbial surface structures, such as the pili of the gonococcus, can "stiff-arm" neutrophils, keeping them at a distance. A number of pyogenic bacteria (*e.g., S. aureus*) secrete leukocidins, which lyse phagocytes. Other pathogens (*e.g.,* group A streptococci) inhibit chemotaxis of neutrophils through the elaboration of enzymes (*e.g.,* C5a peptidase) that proteolytically cleave chemotactic signals. Some bacteria possess mechanisms to prevent opsonization by changing surface antigens.[30] Many bacteria form biofilms, which shield these microorganisms from host defense molecules and antibiotics.[34] Leukocytes that invade *S. aureus* biofilms exhibit impaired phagocytosis and decreased ability to kill bacteria. In addition, biofilm matrices can protect bacteria from antibody-mediated phagocytosis.

As previously noted, many "extracellular" bacteria have an intracellular component to their lifecycle. The intracellular environment provides protection from proteins of the complement system, Igs, and nonspecific barriers to infection present in the epithelia.[28] The entry of bacteria into epithelial cells provides access to nutrients and protection from host defenses, allows protected multiplication, and leads to shedding of organisms back to the mucosal surface, to facilitate transmission and further spread of the infection on the epithelium. Attachment can also initiate epithelial cell apoptosis or toxin-mediated cell death and lead to the breakdown of the epithelial barrier.

HOST RISK FACTORS FOR LOCAL AND SYSTEMIC INVASION BY EXTRACELLULAR PATHOGENS

Bacteria that breach mucosal and skin barriers and reach submucosal tissues of sites, such as pulmonary alveoli or the middle ear and/or the bloodstream, induce immune responses, including cytokine release, phagocytosis, complement activation, antibody release or production, and other local or systemic induction of the inflammatory cascade (Fig. 27.5). The survival of bacteria following colonization of the epithelium and access to the bloodstream depends on the integrity of the host immune response (including variability caused by genetic polymorphisms) and on the ability of the bacteria to resist this host immune response. Host factors that increase the risk for the development of systemic disease as a result of extracellular bacteria include polymorphisms in innate immune mechanisms, the absence of bactericidal or opsonizing antibodies, deficiencies in the complement pathways, and an absence of or reduction in neutrophil function or levels (see Table 27.1).

FIG 27.5 Inflammatory cascade initiated during sepsis.

Complement deficiencies, either congenital or acquired, increase the risk for invasive bacterial diseases (Chapter 21). Because C3 plays a critical role in the complement cascade, congenital C3 deficiency or conditions that reduce C3 (*e.g.,* systemic lupus erythematosus, cirrhosis, nephritis, C3 nephritic factor) increase the risk for invasive disease due to pyogenic bacteria, such as *S. pneumoniae* and *N. meningitidis.* Mannose-binding lectin (MBL) is a plasma opsonin that initiates complement activation. *MBL* gene polymorphisms are found in children with meningococcal and pneumococcal sepsis. Properdin deficiency, leading to defective AP killing, is also associated with severe and recurrent meningococcal infections. Terminal complement deficiencies (C5–C8) are also associated with recurrent invasive bloodstream meningococcal and gonococcal infections, indicating an important role for insertion of the complement MAC in the bactericidal activity of human serum against pathogenic *Neisseria.* In adults, 10–20% of invasive meningococcal disease has been associated with a defect in the complement system.

In infants, antibacterial activity wanes as levels of passively transferred maternal antibody fall. This waning of antibody is correlated with the highest incidence of several "extracellular" pyogenic bacterial diseases (caused by *S. pneumoniae*, *N. meningitidis*, *H. influenzae* type b) in young children. During childhood and adolescence, levels of bactericidal antibodies rise and rates of these diseases decline. Specific antibodies are acquired through carriage and through cross-reacting epitopes on other commensal species. For example, cross-reactive antibodies to *N. meningitidis* are acquired by colonization with commensal *Neisseria* spp. (*e.g., Neisseria lactamica*) and unrelated bacteria (*e.g., Enterococcus faecium*, *Bacillus pumilus*, and *E. coli*). The lack of bactericidal antibodies against a strain recently acquired in the upper respiratory tract is an important risk factor for invasive meningococcal disease.

In addition to defects in innate immunity, Igs, and complement deficiencies, human genetic polymorphisms are associated with an increased risk or severity of bacterial diseases. For example, FcγIIa (CD32) receptor polymorphisms, Fcγ-receptor III (CD16), MBL, TLR4, tumor necrosis factor (TNF) promoter region polymorphisms, plasminogen activator and inhibitor expression, and hereditary differences in cytokine induction influence susceptibility to meningococcemia. Each of these polymorphisms can influence the course of invasive bacterial infection by influencing the response of the inflammatory cascade.

THERAPEUTIC PRINCIPLES

Sepsis

- Early effective antibiotic therapy associated with improved outcomes
- Lack of "source control" (*e.g.,* removal of infected lines, drainage of abscesses) linked to poor outcomes even in the presence of effective antibiotics
- Intensive and supportive care, management of fluid, electrolytes, and respiratory function
- Insulin for glucose control—unknown mechanism of protection; neutrophils have impaired function in the presence of hyperglycemia, insulin can have antiapoptotic effects

DELETERIOUS HOST RESPONSES

Inflammation and Autoimmunity

The host immune response can be the leading cause of tissue injury in the acute phase of an infection. Brain edema and infarcts, which are devastating consequences of pyogenic meningitis, occur as a result of the host inflammatory response. Corticosteroids are currently recommended as an adjunctive therapy to pneumococcal meningitis, an acute pyogenic infection. The use of small molecules targeting specific immunological pathways is an area of ongoing research. As acute infections are initially characterized by an inflammatory response followed by an antiinflammatory response, the timing of use of these compounds is of the utmost importance.[35,36] Infections can lead to autoimmune diseases. Molecular mimicry between a bacterial antigen and a host protein is a mechanism of generation of autoantibodies. Examples include rheumatic fever and glomerulonephritis after *S. pyogenes* infections, reactive arthritis following *Chlamydia trachomatis* urethritis, and the Guillain-Barré syndrome following *Campylobacter jejuni* enteritis. Molecular mimicry can also limit selection of epitopes for vaccine development.

Sepsis

Septicemia remains a leading cause of death in the United States and accounts for several billion dollars in health care expenditure.[35,36] Both gram-negative and gram-positive bacteria can rapidly multiply in the bloodstream and trigger sepsis and septic shock (Table 27.5). Septic shock is a result of an initial and widespread systemic proinflammatory response, resulting in hypotension, organ failure, and death. The later phase of sepsis is also characterized by an antiinflammatory response. Although survival of patients with the acute phase of sepsis has improved, advances on treatment and prevention of death, which can be secondary to nosocomial infections, have been slower. These secondary infections are often caused by less virulent organisms, likely as a result of "immunoparalysis" (as a result of an exaggerated antiinflammatory reaction) and also breaching of the physical barriers to infection as a result of invasive medical procedures (*e.g.,* intravenous lines, intubation, and bladder catheterization). The systemic inflammatory cascade of sepsis is initiated by recognition of PAMPs by PRR, both in extracellular (*e.g.,* LPS) and intracellular environments (*e.g.,* DNA fragments) (see Table 27.3) The severity of sepsis is also influenced by polymorphic alleles of genes involved in the inflammatory cascade.[35]

TABLE 27.5 Examples of Extracellular Bacteria Causing Sepsis by Presumed Site of Infection

Lung	*Streptococcus pneumoniae*, *Haemophilus influenzae*, *Pseudomonas aeruginosa*
Abdomen	*Escherichia coli*, mixed anaerobic infections
Urinary tract	*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Enterococcus* spp.
Soft tissue	*Streptococcus pyogenes*, *Staphylococcus aureus*, polymicrobial
Intravenous line	*S. aureus*, *Candida* spp.
Other	*Neisseria meningitides*

KEY CONCEPTS

Definitions of Sepsis and Septic Shock (Third International Consensus Definitions for Sepsis and Septic Shock)[42]

- Sepsis—life-threatening organ dysfunction causes by dysregulated host response to infections (including nonbacterial pathogens)
- Septic shock—subset of patients with sepsis with increased risk of death due to profound circulatory, cellular, and metabolic abnormalities
- SIRS (systemic inflammatory response syndrome)—nonspecific response to infectious and noninfectious insults; current guidelines recommend use of qSOFA (Quick Sequential Organ Failure Assessment Score) score in lieu of SIRS criteria, given its higher predictive value for sepsis

The morbidity and mortality of bacteremia and sepsis have been directly correlated with the initial levels of proinflammatory cytokines and the amount of circulating bacterial components. Indeed, the severity of gram-negative sepsis has been equated with high levels of endotoxin, increased levels of cytokines, and excessive activation of the AP. Disseminated intravascular coagulation, which often accompanies gram-negative sepsis, is caused by excessive activation of the coagulation cascade and downregulation of the fibrinolytic system associated with high levels of LPS. Levels of natural anticoagulants in the vasculature, such as antithrombin and protein C, are often low in gram-negative sepsis. The onset and severity of disseminated intravascular coagulation may be influenced by genetic polymorphisms in plasminogen activation or inhibition. The generalized, altered vascular endothelial lining facilitates thrombosis and thrombocytosis. Although much remains to be learned about the mechanisms by which gram-negative and gram-positive bacteria and microbial products trigger sepsis, significant advances have been made recently, particularly with endotoxin-mediated sepsis. Advances during the past decade include the identification of certain LPS–host protein interactions that result in delivery of LPS to host cell receptors and gene activation events that result in elevated expression of a diverse array of proinflammatory and antiinflammatory mediators (Fig. 27.6).

For example, TLR4 signaling requires an accessory protein, myeloid differentiation protein-2 (MD-2), which binds directly to endotoxin.[37] The key point, however, is that the LPS engagement

of MD-2/TLR4 on host cells, particularly macrophages, triggers intracellular signaling events that ultimately, through NF-κB and other pathways, result in cytokine gene activation and production of cytokines (TNF-α, IL-1, IL-6, IL-8, IFNs). Other TLRs (*e.g.*, TLR2) play a critical role in the recognition of lipoproteins, and the recognition of these components is a likely a key determinant in the development of septic shock seen with gram-positive infections. TLR5 recognizes bacterial flagella, and such recognition is of importance in the host response to motile bacteria. Some human pathogens (*e.g.*, *H. pylori*) produce flagellin molecules that do not engage TLR5. TLR9 has been shown to recognize bacterial DNA CpG dinucleotides.[14] Taken together, the clinical syndrome of septic shock represents a series of interactions of bacterial products in the vascular space with pattern recognition molecules on serum proteins (Lipopolysaccharide-binding protein [LBP] and soluble CD14) and with host cell receptors (MD-2/TLR4 and TLR2, other TLRs) leading to signaling events and release of transcriptional factors that modulate cytokine gene expression. These events also trigger other events in the inflammatory cascade, leading to activation of the coagulation, complement, and kinin pathways. Superantigens can activate large pools of non–antigen-specific T cells by binding to MHC class II molecules and the TCR Vβ region outside the peptide-binding domain. The result is a cytokine storm with clinical manifestations of sepsis.

Early and effective antimicrobial therapy is the primary goal in the treatment of sepsis. In contrast to the initial phase of sepsis characterized by the release of TNF-α, IL-1, IL-6, and IFN-γ, an antiinflammatory response may predominate during the latter phase. The clinical failures of antiinflammatory therapeutic mediators (antiendotoxin antibodies, TNF-α, antagonists of IL-1, or platelet-activating factor) in sepsis suggests that this hypoinflammatory state encountered in many patients at presentation could be an additional target of immune modulation.

CLINICAL RELEVANCE

Signs of Septicemia

- Shaking chills, spiking fevers, or hypothermia (<36°C)
- Tachycardia, hyperventilation
- Pallor (peripheral vasoconstriction) and acrocyanosis, but 10–20% are flushed "warm shock"
- Nausea/vomiting, diarrhea
- Hypotension <90 mm Hg or >40 mm Hg decrease from baseline, in 20–35% of cases
- Cardiac output, decreased systemic vascular resistance (SVR)
- Cutaneous signs: purpura fulminans, petechiae, palpable purpura, ecthyma gangrenosum
- Change in mental status
  - Signs may be more subtle in elderly and uremic (renal failure) patients
  - White blood cell (WBC) count >12 000 cells/mm^3 or <4000 cells/mm^3 with >10% immature (band) forms
  - Oliguria (<20 mL/h of urine)

ENHANCEMENT OF IMMUNE RESPONSES TO EXTRACELLULAR BACTERIA (VACCINES AND IMMUNOMODULATION)

Vaccines are the most affordable and cost-effective health intervention for enhancing the immune response to extracellular bacterial and other microbial pathogens (Chapter 90). The use of vaccines to prevent diphtheria, pertussis, tetanus, and infections by *N. meningitidis*, *H. influenzae* b (Hib), and *S. pneumoniae* is a major public health success. Vaccines are also used for prevention of disease caused by *Salmonella typhi*, *Vibrio cholera*, and *Bacillus anthracis.* The efficacy of vaccines to extracellular bacteria is most often correlated with enhanced bactericidal antibodies, opsonic antibodies, and/or neutralizing antibodies, both systemically and at mucosal surfaces. Enhancement of these immune mechanisms can provide protection even in immunocompromised individuals (although immune responses are diminished in these individuals). For example, vaccination with meningococcal capsular vaccines protect patients with hereditary complement deficiencies by enhancing opsonophagocytic activity. However, vaccines have limitations in terms of long-lived immune responses, safety issues, and poor responses in certain populations (extremes of age) when infections with extracellular bacteria are most common. Advances in genetic engineering, immunology, molecular pathogenesis, vaccine adjuvants, and delivery systems are resulting in the development of new vaccines and vaccine approaches that enhance the immune response to extracellular bacterial pathogens (*e.g.*, protein–polysaccharide conjugate vaccines for Hib, *S. pneumoniae*, and *N. meningitidis*).

The conjugation of bacterial polysaccharides to carrier proteins, such as diphtheria or tetanus toxins, has been a major advance in stimulating immune responses to saccharide bacterial antigens. Polysaccharide capsules, for example, when used alone, are "T-independent" antigens; they do not require the presence of T cells to induce an immune response, and generate IgM as the dominant antibody produced (Chapter 6). Failure to induce memory and failure of affinity maturation follow polysaccharide immunization. Thus polysaccharides are poorly immunogenic in infants, older adults, and those with impaired antibody production—groups most susceptible to encapsulated bacterial pathogens. Covalent linkage of the polysaccharide to a carrier protein converts the polysaccharide to a thymus-dependent antigen generating IgG anticapsular antibodies and memory B cells. Because these vaccines induce vigorous mucosal immune responses, they also provide "herd" protection. A major (and unanticipated) result of vaccination with the Hib, meningococcal, and pneumococcal conjugate vaccines is the interruption of mucosal carriage, decreased transmission, and herd protection. These vaccines are now used as part of the routine immunization series in all age groups.

The presentation to CD4 T cells of an antigen by MHC class II molecules is critical for an immune response and influences the amount of antibody, the affinity of that antibody, and the duration of response. CD4 T cell subsets influence the qualitative and quantitative features of an immune response to vaccines and bacterial antigens. As new subsets of CD4 T cells are described, research is necessary to determine their role in existing vaccines and strategies to exploit them in new preparations (Chapter 16).[38] Mucosal vaccination is an attractive strategy for protection against extracellular bacteria as mucosal colonization often precedes invasive disease. The hope is to generate effective immune responses at the mucosa and avoid the need for parenteral injection.[39] In addition, recent advances in the application of systems biology to define molecular signatures that correlate with and predict vaccine immunity have greatly enhanced our understanding of immune responses to vaccination.[40]

Considerable progress is being made in the development of new vaccine adjuvants and immune modulators (see Chapter 90 for updated information). Aluminum salts, used since the 1930s in many vaccines against bacteria, induce a >90% Th2 response. As noted above, bacterial toxins as conjugates can be used to enhance immunogenicity. In addition, saponin adjuvants, liposomes, CpG DNA repeats, and TLR agonists are in use or under development as adjuvants. Monophosphoryl lipid A (MPL), long known to be an effective adjuvant in animal models, is now approved for human use, as an oil-in-water emulsion containing squalene. Cytokines, such as IL-1, IL-2, IL-12, IL-18, and granulocyte macrophage–colony-stimulating factor (GM-CSF), also modify and enhance immune responses to vaccines. IL-12, for example, induces strong Th1 shifts, and GM-CSF is a comigrating signal for DCs and stimulates antigen processing and presentation. Antigen recognition and processing in macrophages is critical to determining T-cell responses and can be manipulated by selected adjuvants. Immune modulation is being evaluated not only for the enhancement of bacterial vaccines but also as adjunct therapy for serious bacterial infections, such as sepsis. Vaccines and specific immunotherapeutic approaches, such as cytokines, may also find use against chronic tissue-damaging inflammatory reactions created by persistent extracellular bacteria (*e.g.*, *Helicobacter*) and autoimmune reactions that may be induced by cross-reactive bacterial antigens (*e.g.*, *C. jejuni* and Guillain-Barré syndrome).

TRANSLATIONAL RESEARCH OPPORTUNITIES

An important challenge for the next decade will be to take the rapidly expanding basic discoveries in innate immunity, systems biology, and response to bacterial antigens into clinical applications. The design and use of bacterial vaccines through the assessment of innate immune molecular signatures after vaccination, both for general use and for subpopulations of nonresponders, is one example. A second is the continued development of small-molecule inhibitors or enhancers that specifically target innate immune pathways to modulate bacterial immune responses. A third is the control of mucosal immune responses to prevent or eliminate colonization by bacterial pathogens. A fourth is the understanding of role of the microbiome in shaping the immune response to pathogens and vaccines and its therapeutic potential for both infections and noninfectious diseases. Fecal microbiota transplantation for *C. difficile* colitis is an early example of therapeutic use of the microbiome. Finally, the development of new therapies for acute bacterial sepsis may be based on improved understanding and control of the immune responses in sepsis.[36]

ON THE HORIZON

- Tailoring vaccine design based on assessment of innate immune molecular signatures
- Small molecule inhibitors or enhancers specifically targeting innate immune pathways
- Identification of immune responses that prevent or eliminate mucosal bacterial pathogen colonization
- Development of new therapies modulating immune response in sepsis
- Defining microbial community and metagenome changes after antibiotic treatment
- Managing disease based on the human microbiome

MULTIPLE-CHOICE QUESTIONS

1. With regard to the use of corticosteroids as adjunctive therapy for acute infections:
   - **A.** Corticosteroids are immunosuppressive and should be avoided during acute infections.
   - **B.** Corticosteroids are generally recommended for the treatment of sepsis.
   - **C.** Corticosteroids are never contraindicated during acute infections.
   - **D.** Corticosteroids are beneficial in certain types of acute infection, presumably because of their antiinflammatory effect.

2. A 18-year-old college freshman presents to the hospital with meningococcal meningitis. Upon review of his medical history, you learn that he had disseminated gonococcal infection at the age of 16 years. Should you consider investigation for an immunodeficiency? If so, which one? Should you offer any prophylactic therapies for this patient?
   - **A.** No investigation for an immunodeficiency is warranted. Meningococcal vaccination should be offered.
   - **B.** These infections suggest a T-helper (Th)17 deficiency, and there is no approved prophylactic therapy for this disorder.
   - **C.** This patient should have diagnostic workup for terminal complement deficiencies. Meningococcal vaccination should be offered.
   - **D.** This patient should have diagnostic workup for terminal complement deficiencies. If confirmed, stem cell transplantation can be offered.

3. The normal microbiota maintains a balance with the host by avoiding activation of pathogen recognition receptors. Pathogen recognition receptors are activated by pathogenic bacteria only.
   - **A.** False. Colonizers and pathogens have pathogen-associated molecular patterns, and both can activate pattern recognition receptors.
   - **B.** True. Colonizers are devoid of pathogen-associated molecular patterns.
   - **C.** True. Colonizers have pathogen-associated molecular patterns but do not activate pathogen recognition receptors.
   - **D.** False. Colonizers and pathogens have pathogen-associated molecular patterns, and both can activate pattern recognition receptors, but colonizers only do so when invading host tissues.

Host Defenses to Spirochetes

Nicolás Navasa, Erol Fikrig, Juan Anguita

Spirochetes constitute a unique group of bacteria that inhabit many different environments, such as soil, arthropods, and mammals. These microorganisms cause numerous human illnesses, including syphilis and Lyme disease. Spirochetes share a typical spiral shape and a distinctive flat-wave morphology. Cellular dimensions vary over a wide range, with a diameter between 0.09 to 0.75 μm and lengths that range from 3 to 500 μm. They are motile organisms with a multilayered outer membrane that encapsulates a peptidoglycan layer surrounding their inner membrane. Motility is enabled by the presence of endoflagella located in the periplasmic space. These axial filaments are arranged in a bipolar fashion and extend toward the opposite end of the cell (Fig. 28.1). The viability of the organism is dependent on an intact outer membrane, which can be damaged by variations in osmolarity, antibodies, or complement resulting in the loss of intracellular components and ultimately death of the bacterium.

Several spirochetal species are able to induce disease in mammals (Table 28.1). Lyme disease was first discovered in 1976 as an illness affecting a cluster of children in Lyme, Connecticut. Several manifestations of the disease, however, had been known for over a century in parts of Europe. In 1982, the agent of Lyme disease was identified as *Borrelia burgdorferi.*[1] In contrast, *Treponema pallidum* subspecies *pallidum* is the causative agent of venereal syphilis, a disease that has been recognized for over 5 centuries, although its agent was not identified until 1905.[2]

The genomes of *B. burgdorferi* and *T. pallidum* have been sequenced.[3,4] Despite similar ancestry and morphological features, these spirochetes have striking differences at the genetic level, which may account for the differences in their lifecycles, environmental adaptations, and the diseases they cause. Both *B. burgdorferi* and *T. pallidum* have relatively small genomes compared with other microorganisms. *B. burgdorferi* has one of the most complex genomes known among prokaryotes, with a single linear chromosome and 21 plasmids, the largest number of plasmids of any characterized prokaryote. Of the 21 plasmids, nine are circular and 12 are linear. Furthermore, less than 10% of *B. burgdorferi* plasmid-coding regions are found in other microorganisms, including spirochetes, which underscore the uniqueness of this spirochete among microorganisms. Unlike *B. burgdorferi, T. pallidum* contains a single circular chromosome with no plasmids. Yet, 476 open reading frames (ORFs) in *T. pallidum* have orthologous genes in *B. burgdorferi,* and almost 60 of these orthologous genes encode proteins of unknown biological function that are specific to spirochetes.

In contrast to other spirochetes, *B. burgdorferi* and *T. pallidum* do not contain lipopolysaccharide (LPS). Lipoproteins are the major immunogens of *B. burgdorferi* and most likely *T. pallidum,* and thus they are their dominant proinflammatory agonists. Five percent of the chromosomal ORFs and 14.5–17% of the functionally complete ORFs contained in the plasmids of *B. burgdorferi* encode putative lipoproteins. Interestingly, only 2.1% of the *T. pallidum* ORFs encode putative lipoproteins. The abundant lipoprotein coding potential of *B. burgdorferi* suggests that these molecules may be important for the survival of the spirochete. In fact, as a result of environmental changes, expression of several *B. burgdorferi* lipoproteins changes throughout the lifecycle of the spirochete.[5] For instance, the lipoprotein outer surface protein (Osp) A is expressed at high levels in the gut of the unfed tick, but upon feeding OspA expression is downregulated, and the expression of OspC increases 90-fold.[5] It is thought that many Osps have adhesive functions, and it has been shown that OspA is involved in the attachment of *B. burgdorferi* to the gut of the tick through an interaction with the tick receptor TROSPA.[6] Furthermore, OspC may be necessary for the migration of *B. burgdorferi* from the gut of the tick to the salivary glands and for its survival in the mammalian host. Changes in lipoprotein expression are primarily regulated by the alternative sigma factors, RpoS and RpoN[7] and other unknown mechanisms.

CLINICAL MANIFESTATIONS

Lyme Disease

B. burgdorferi sensu stricto (*B. burgdorferi*) is the etiological agent of Lyme disease in the United States and other parts of the world, whereas *B. afzelii* and *B. garinii* are agents of Lyme disease that are restricted to Europe and Asia. Infection with Lyme disease–causing spirochetes has also been observed in Japan, Russia, and China. In the United States, transmission of the spirochete is through the hard-bodied ticks of the *Ixodes* complex, mainly *I. scapularis* and *I. pacificus,* whereas *I. ricinus* is responsible for the transmission of the spirochete in much of Eurasia. According to the Centers for Disease Control and Prevention (CDC), Lyme disease is the most common tickborne disease in the United States and the fifth most common nationally notifiable disease.[8] The disease is concentrated in the North Eastern seaboard, with further presence in the northern Midwest and the West of the Continental United States. In Europe, diagnosed Lyme disease accounts for more than 65 000 cases annually, which tend to concentrate in countries of Central and Eastern Europe. However, the disease is present to different degrees throughout much of Europe. In both the United States and Europe, it is widely believed that the disease is underreported and that the suspected real number of cases may be much higher.

An early hallmark of infection is the appearance of a skin rash, known as erythema migrans (Fig. 28.2), which appears at the inoculation site, often during the first week of infection (stage I Lyme disease), as a result of local inflammatory responses. Other symptoms secondary to the local inflammatory responses occurring during stage I can affect more distal sites and may include fever, headache, malaise, myalgia, and/or arthralgia. Hematogenous dissemination of the spirochete is stage II Lyme disease and results in colonization of different tissues and/or organs and presentation of a range of symptoms, such as conduction system abnormalities, meningitis, and acute arthritis. Joint inflammation appears in 60% of untreated individuals in the United States and predominately affects large joints, especially the synovium of the knee. Some untreated individuals develop stage III Lyme disease, which is generally characterized by prolonged infection with the spirochete. Late-stage symptoms may include chronic arthritis, neuroborreliosis, or cutaneous lesions, such as acrodermatitis chronica atrophicans. The range of symptoms that appear upon infection in Europe and the United States vary in relative terms: arthritis and carditis are

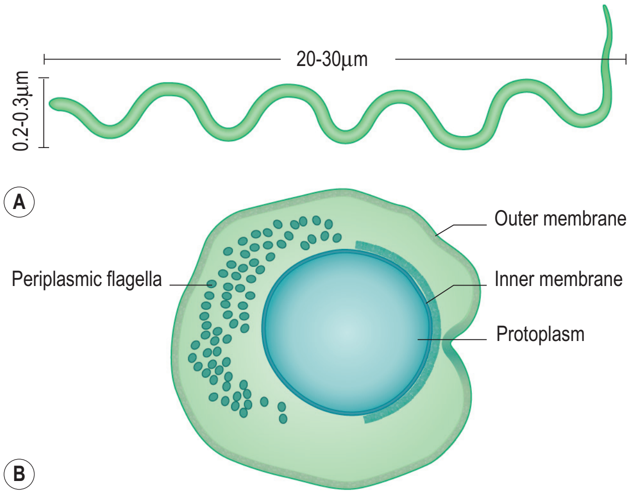

FIG 28.1 *Borrelia burgdorferi* structure is characterized by a distinctive flat-wave morphology consisting of approximately 18 bends and a length of 20–30 µm (A). A cross-section of this spirochete reveals the endoflagella, which are responsible for the unique morphology and motility of this organism (B).

TABLE 28.1 Major Diseases Caused by Spirochetes*

Disease	Agents	Distribution	Transmission	Symptoms
Lyme disease	*Borrelia burgdorferi*	North America, Europe	Tick engorgement	Development of a skin rash known as *erythema migrans,* accompanied by other symptoms, such as malaise, myalgia, and/or arthralgia. Symptoms can progress to include carditis and arthritis. Persistent infection can result in chronic arthritis, neuroborreliosis, or cutaneous symptoms (acrodermatitis chronica atrophicans).
	B. garinii	Asia, Europe		
	B. afzelii	Asia, Europe		
	B. andersonii	North America		
	B. japonica	Japan		
	B. lusitaniae	Southern Europe		
	B. valaisiana	Europe, Ireland, UK		
	B. mayonii	North America		
	B. miyamotoi	North America		
Relapsing fever	*B. hermsii*	Western USA	Tick engorgement	Clinical manifestations of infection include high-density spirochetemia, high fever, myalgias, and arthralgias and can even include cerebral hemorrhage and fatality.
	B. turicatae	Southwestern USA, Mexico		
	B. parkeri	Western USA		
	B. mazzotti	Central America		
	B. venezuelensis	Central America		
	B. duttonii	Sub-Saharan Africa		
	B. crocidurae	North Africa, Middle East		
	B. persica	Middle East, Central Asia		
	B. hispanica	Iberian peninsula, North Africa		
	B. latyschewii	Iran, Iraq, Eastern Europe		
	B. caucasia	Iraq, Eastern Europe		
Venereal syphilis	*Treponema pallidum pallidum*	Worldwide	Sexual contact	Disease progresses from a primary lesion (chancre) to a secondary eruption and then to a latent period, and if left untreated, tertiary symptoms may appear.
Endemic syphilis or Bejel syphilis	*T. pallidum endemicum*	Eastern Mediterranean region, West Africa	Nonsexual skin contact	Symptoms begin with a slimy patch inside the mouth, followed by blisters on the trunk and limbs. Bone infection in the legs soon develops, and in the later stages, lumps may appear in the nose and on the soft palate of the mouth.
Yaws	*T. pertenue*	Humid equatorial countries	Nonsexual skin contact	Destructive lesions of the skin and bones, which is rarely fatal but can be debilitating.
Pinta	*T. carateum*	Mexico, Central America, South America	Nonsexual skin contact	Dark-colored skin lesions found on those areas of the body that are exposed to sunlight. Eventually, the skin lesions become discolored.
Leptospirosis	*Leptospira interrogans*	Worldwide	Urine from an infected animal	Symptoms include fever, headache, chills, nausea and vomiting, eye inflammation, and muscle aches. In more severe cases, the illness can result in liver damage and kidney failure.

*Spirochetes are the causative agents of many diseases, which can have social as well as lasting health-related consequences.

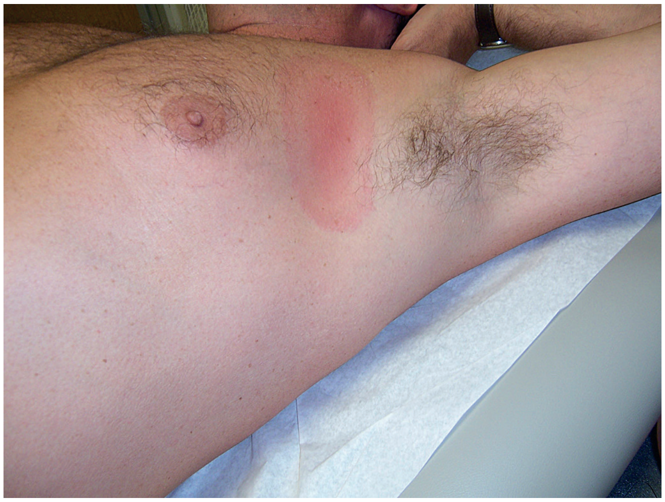

FIG 28.2 *Erythema migrans* caused by infection with *Borrelia burgdorferi,* the Lyme disease agent. (Courtesy of Gary Wormser, MD.)

more commonly found in the United States, whereas patients in Europe tend to show higher incidence of skin and nervous system involvement. This may be attributed to the heterogeneity of the *B. burgdorferi sensu lato* genospecies that cause the disease. In the United States, in the large majority of cases, *B. burgdorferi sensu stricto* is involved, whereas in Europe infections by *B. afzelii* and *B. garinii* predominate.

Diagnosis

A detailed clinical history and comprehensive physical examination are critical for the accurate diagnosis of Lyme disease. Appropriate laboratory testing, however, is a valuable diagnostic aid. A two-tiered approach is standard for the serodiagnosis of Lyme disease. Using this approach, serum is first tested for the presence of *B. burgdorferi*–specific antibodies by using a sensitive method, such as enzyme-linked immunosorbent assay (ELISA) or immunofluorescent assay (IFA). Sera testing negative for antibodies generally need not be tested further; however, those found to be positive or equivocal are further evaluated by the more specific immunoblotting for immunoglobulin M (IgM) and IgG antibodies. The detection of at least two of three specific bands in IgM or five of 10 specific bands in IgG is considered positive. Patients with early Lyme disease often report to a physician during the first few days of infection, at which time a detectable humoral response may not have developed. Consequently, the two-tiered approach is considered highly sensitive during the later stages of the disease (>90%) and less sensitive during very early infection. Furthermore, a positive serological test, particularly IgG, is evidence of exposure to *B. burgdorferi,* but it does not necessarily indicate active infection. All serological tests must then be evaluated in conjunction with a clinical assessment by the attending physician. Other diagnostic methods, such as culture and polymerase chain reaction (PCR) detection of *B. burgdorferi,* may be very useful to detect active infection, particularly of skin, joints, and the central nervous system (CNS). Culture, however, is generally limited to research laboratories, and the sensitivity and specificity of PCR can vary greatly among testing centers.

Treatment

During early stages of Lyme disease, such as that during which *erythema migrans* is present, oral administration of doxycycline (100 mg twice daily) or amoxicillin (500 mg three times a day) for approximately 2 weeks is recommended. Doxycycline has the advantage of being effective against *Anaplasma phagocytophilum,* which may also be transmitted by ticks. In areas where *B. burgdorferi* infection is prevalent, some experts recommend antibiotic therapy for individuals who served as hosts to *I. scapularis* ticks that were attached longer than 40–48 hours—the time required for transmission of the spirochete. It is extremely difficult, however, to consistently make accurate determinations of the species of tick and the degree of engorgement. Furthermore, randomized double-blind clinical trials involving individuals who were bitten by *I. scapularis* ticks led to the conclusion that antibiotic treatment of all individuals who had vector ticks removed is probably not warranted.

Venereal Syphilis

Infection with the agent of syphilis, *T. pallidum* subspecies *pallidum,* occurs worldwide. *T. pallidum* is an obligate human parasite that is almost exclusively transmitted when contact with infectious exudates from lesions of the skin and mucous membranes of infected individuals occurs. Clinically, this treponemal infection is first characterized by the formation of a hardened and painless ulcer at the initial site of infection. This primary lesion, called a *chancre,* forms after invasion of the bloodstream by the spirochete. Four to 6 weeks after infection, the edges of the chancre roll inward and upward and, in most cases, a secondary eruption appears, often accompanied by a rash on the palms of the hands and the soles of the feet. The secondary manifestations resolve within weeks to a year after the development of a vigorous cell-mediated immune response. Long periods of latency followed by late lesions of skin, bone, and viscera, as well as the cardiovascular system and the CNS, can occur despite clearance of the majority of the treponemes, which coincides with the resolution of the primary syphilitic lesion.

Diagnosis

Much like Lyme disease, the diagnosis for syphilis is based on the clinical presentations of the disease and serological tests. In addition, dark-field microscopy can be used for the identification of *T. pallidum* in the serous exudates of the chancre. This approach, however, is limited by the number of live treponemes in the exudates and by the presence of nonpathological treponemes in oral and anal lesions; as such, negative examinations on three independent days are required before a lesion is considered negative for *T. pallidum.*

Infection with *T. pallidum* leads to the production of nonspecific antibodies, which is the basis for other diagnostic tests, such as the traditional nontreponemal serological tests, including the Venereal Disease Research Laboratory (VDRL) and rapid plasma reagin (RPR) tests. Because these tests are nonspecific, false-positive reactions can occur as a result of pregnancy, autoimmune disorders, or infections. Therefore treponemal-specific tests, which detect antibodies to various antigens of *T. pallidum,* are often used to confirm the results of a nonspecific test. Interestingly, treponemal-specific tests are just as sensitive as nontreponemal tests; however, they are much more difficult and expensive to perform, which limits their use. These tests include, but are not limited to, the enzyme immunoassay (EIA) test for *T. pallidum*-specific IgG, *T. pallidum* hemagglutination test (TPHA), fluorescent treponemal antibody-absorption test (FTA-ABS), and ELISA.

Treatment

Susceptibility to infection with *T. pallidum* is universal, although only 30% of exposures with lesions teeming with the spirochete result in infection. Infection results in gradual development of immunity against *T. pallidum* and often against heterologous treponemes as well. However, treatment with long-acting penicillin subverts the development of immunity against *T. pallidum*. Administration of 2.4 million units in a single intramuscular dose the day that the primary, secondary, or latent syphilis is diagnosed is effective at killing the spirochetes. For people who are allergic to penicillin, there are alternative treatments, such as doxycycline.

HOST DEFENSES TO *B. burgdorferi*

KEY CONCEPTS

Protective Versus Pathological Responses to Borrelia burgdorferi

The early immune response to *B. burgdorferi* is necessary to control spirochetal burden; however, by itself, it is not sufficient to resolve infection.

Phagocytosis is a key element of the innate immune response, which is involved in the elimination of the bacteria while also contributing to the proinflammatory output of macrophages

The T cell–mediated response appears to be involved in pathology arising from infection.

A T cell–independent B-cell response is sufficient to resolve infection with *B. burgdorferi.*

B. burgdorferi virulence is attributed, in part, to the evolution of the spirochete's sophisticated tactics to evade killing mechanisms during all stages of the immune response: the first stage, beginning with transmission into the host via tick engorgement, at which time the spirochete is exposed to serum complement and cellular immunity; and the second and third stages, that is, hematogenous dissemination to and colonization of peripheral sites, at which time the host is producing specific antibodies. Both the innate and adaptive immune responses elicited by *B. burgdorferi* are discussed, with the supposition that these responses are required for efficient bacterial clearance, while acknowledging that unnecessarily prolonged or intense responses may contribute to pathology arising from infection. Indeed, predisposition to infection could be the result of one or more monogenic traits that confer primary immunodeficiencies; whether or not this is the case remains to be determined, but human studies have shown that responses to *B. burgdorferi* are diminished in individuals with specific mutations in or diminished expression of innate immune cell receptors (nucleotide-binding oligomerization domain-2 [NOD2] and Toll-like receptor-1 [TLR1]).

Innate Immune Responses

The initial recognition of pathogens with cells of the host relies on a complex interplay between pathogen recognition receptors (PRRs) and bacterial constituents, and this initiates a cascade of responses leading to the upregulation of chemokines and cytokines, adhesion molecules, and other effector molecules (Chapter 3). This response is often initiated by endothelial and/or epithelial cells, resulting in the recruitment of different types of innate immune cells and their activation. Each PRR recognizes a specific structure that is present in a group or groups of microorganisms and that distinguishes them from the more specific recognition of antigens by the T- and B-cell receptors. The recognition of patterns instead of specific antigens provides the innate immune system with a rapid way to respond to infecting organisms until the more specific response mediated by T and B cells develops.

A distinct innate cellular infiltration profile has been observed in *B. burgdorferi*–infected tissues. Based on studies using mice, the inflamed heart appears to predominately comprise macrophages, with smaller amounts of T and invariant natural killer T cells (iNKT cells). However, neutrophils are the primary innate immune cell found in the joints. In this tissue, resident myeloid cells act as the initiators of type I interferon (IFN) production upon encounter with *B. burgdorferi,* whereas endothelial cells and joint fibroblasts expressing adhesion/ activation markers amplify the response and serve as the major source of disease-promoting chemokines. This tissue-specific tropism complicates our understanding of the host defense against the spirochete, but this suggests that macrophages are more efficient at preventing successful colonization of *B. burgdorferi* because carditis is a less frequent manifestation of Lyme disease. These early defense responses also have a role in determining the type, strength, and duration of the more specific adaptive immune response, beyond their direct bacterial-killing capability.

Early Pathogen Recognition

The interaction of *B. burgdorferi* lipoproteins with complexes formed by TLRs 1 and 2 initiates a series of signaling cascades that results in the production of proinflammatory cytokines (IL-1β, tumor necrosis factor [TNF], interleukin [IL]-12, and IL-18, among others), chemokines (IL-8, monocyte chemoattractant protein [MCP]-1, keratinocyte chemoattractant [KC]), metalloproteinases, adhesion molecules (E-selectin, vascular cell adhesion molecule-1 [VCAM-1] and intercellular adhesion molecule-1 [ICAM-1]),[9] and type I IFNs. These interactions are critical for generating an effective spirochete-clearing inflammatory response, as demonstrated by experiments using mice deficient for TLR1, TLR2, or their adaptor molecule, MyD88. These mice had significant increases in *B. burgdorferi* burdens after infection. Moreover, humans with decreased TLR1 expression are hyporesponsive to the original OspA-based Lyme disease vaccine, and macrophages from these subjects also have diminished inflammatory responses to the lipoprotein. Besides TLR1/TLR2 complexes, other members of this family of receptors participate in, and amplify, the inflammatory response to *B. burgdorferi.* These include TLR5, TLR7, TLR8, and TLR9, which recognize different bacterial constituents. Importantly, the development of inflammatory arthritis in the absence of TLRs or MyD88 was the first suggestion that alternative pathways trigger the inflammatory response to the spirochete. Other PRRs that have been shown to be involved in the response to the spirochete include NOD-like receptors. For the full inflammatory response to take shape upon recognition of *B. burgdorferi,* most of the interactions of *B. burgdorferi* constituents and PRRs occur within the phagolysosome. Therefore phagocytosis is a hallmark of the innate immune cell recognition of the spirochete.

The interaction of several cell types with the spirochetes also involves several integrins belonging to the β_1, β_2, and β_3 groups. Integrins are involved in the adhesion of cells to a variety of

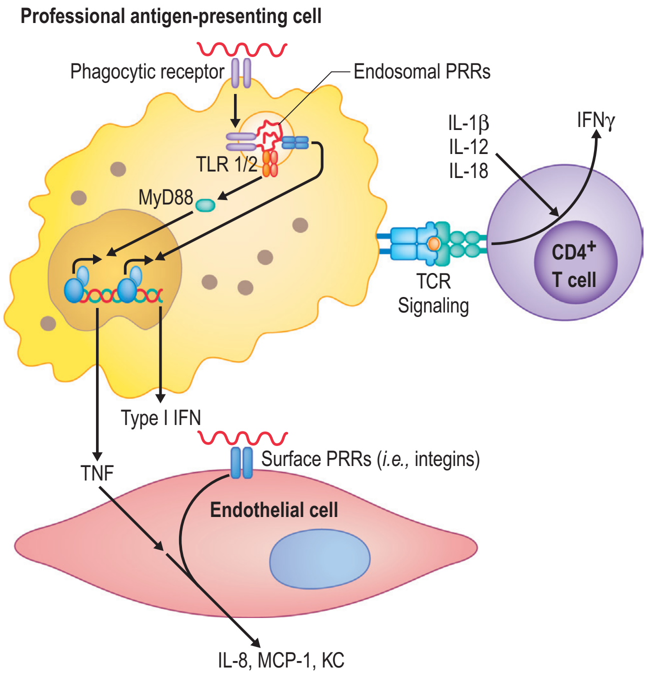

FIG 28.3 The interaction of *Borrelia burgdorferi* with pattern recognition receptors (PRRs) in innate immune cells and endothelial cells mediates the inflammatory response to the spirochete. Phagocytosis induces Toll-like receptor (TLR)–driven proinflammatory cytokine production as well as antigen presentation by professional antigen-presenting cells (APCs), which leads to the activation of CD4 effector T cells, marked by the production of IFN-γ. Likewise, PRR- and tumor necrosis factor (TNF) receptor signaling lead to the upregulation of chemokines by endothelial cells. Overall, these responses lead to increased activation and recruitment of innate immune cells in sites of infection.

ligands and mediate essential cellular processes, including attachment and cell migration. Some integrins have also been associated with the phagocytosis of microorganisms. For the most part, study of the interaction between the spirochete and integrins has focused on their role aiding the adhesion of *B. burgdorferi* to cells and the colonization of tissues and as receptors that contribute to signals that induce the production of proinflammatory factors (Fig. 28.3).

Phagocytic Cell Recruitment and Spirochetal Clearance

The recruitment of phagocytic cells and other cell types into sites of infection is mediated by the production of chemokines, increased vascular permeability, and upregulated expression of cell adhesion molecules in endothelial cells. *B. burgdorferi* induces the upregulation of these factors in different cell types. Chemokine production at sites of pathology in disease-susceptible C3H/HeJ mice and disease-resistant C57BL/6 J mice shows that inflammation is related to increased production of neutrophil and monocyte–macrophage chemokines, KC and MCP-1, respectively. In patients, the production of chemokines, especially IL-8, during the initial response to *B. burgdorferi* correlates well with the onset of symptoms known to occur during the early stages of infection, and this suggests that their production is increased during the beginning of the infection to recruit phagocytic cells, which are involved in the initial clearance of the spirochete.

Little is known about the molecular events or receptors that mediate *B. burgdorferi* phagocytosis despite the importance of this cardinal mechanism of pathogen clearance. MyD88-mediated signals substantially mediate the phagocytosis of *B. burgdorferi.* However, MyD88-mediated phagocytosis occurs independently of any known *B. burgdorferi*-recognizing TLRs. The mechanism of MyD88-mediated phagocytic uptake is therefore unclear. Furthermore, the analysis of MyD88-deficient macrophages shows that although reduced, phagocytosis is not absent in these cells. Therefore the uptake of *B. burgdorferi* by phagocytic cells seems to be mediated by more than one receptor with MyD88-dependent and MyD88-independent components. Complement receptor 3 (CR3) is a β_2 integrin, which, in cooperation with the GPI-anchored CD14, acts as a phagocytic receptor for *B. burgdorferi* independently of TLR or MyD88-induced signals.[10] Phagocytosis plays a major role in the pathogenesis of Lyme disease, not only through the control of bacterial numbers but also through modulation of the potency and quality of proinflammatory cytokine induction. Indeed, as opposed to MyD88-mediated phagocytosis, which is proinflammatory, the internalization of *B. burgdorferi* by CR3 tempers the inflammatory response of macrophages. Therefore the presence of alternative phagocytic mechanisms has nonredundant physiological consequences during infection with the spirochete.

Complement

The complement system is a key component of the innate immune system (Chapter 21). It comprises a collection of serum proteins and cell surface receptors that are involved in the early response to pathogens, including *B. burgdorferi.*[11] Destruction of microorganisms via complement involves the formation of a pore in the microbial cell membrane by the membrane attack complex (MAC), which results in the lysis of the organism. Three different pathways elicit complement activation: the classical (antigen/antibody–mediated) pathway (CP), the lectin pathway, and the alternative (pathogen surface) pathway (AP). These pathways converge at the level of C3 convertase, a protease that cleaves complement component C3 into C3a and C3b. As a result, C3b can (i) bind to the surface of the bacteria and facilitate internalization of the spirochete via opsonization; or (ii) it can bind C3 convertase and facilitate the deposition of downstream components onto the surface of the spirochete resulting in the formation of MAC and lysis of the cell.

B. burgdorferi activates the CP and AP of the complement cascade.[12] Moreover, the activation of complement has been associated with dramatic decreases in spirochetal numbers in different tissues of infected mice, indicating the importance of the complement system early in *B. burgdorferi* infection.

The members of the *B. burgdorferi sensu lato* group, which includes *B. burgdorferi sensu stricto, B. garinii,* and *B. afzelii,* have evolved a variety of mechanisms enabling them to escape complement-mediated lysis, including the expression of complement regulator-acquiring surface proteins (CRASPs). Of these CRASPs, the Erp (OspEF-related protein) family of outer membrane proteins serve as binding sites for the complement inhibitor factor H and factor H–like protein 1 (FHL-1).[13] The interaction of factor H with these proteins recruits a protease (factor I) that cleaves and inactivates the complement serum proteins, C3b and C4b. Cleavage of these two complement proteins prevents the deposition of downstream components onto the surface of the spirochete, thereby halting the formation of the membrane attack complex. *B. burgdorferi* also express a CD59-like molecule on the outer membrane that can inactivate MAC and prevent complement-mediated lysis.[14] It has been speculated that most borreliae are able to evade complement-mediated lysis, and recently, a novel protein expressed by *B. hermsii* (a relapsing fever spirochete) has been discovered that affords protection to spirochete by inactivating C3b.[15] More recently, it has been shown that *B. burgdorferi* expresses a protein, BBK32, on its surface, which prevents activation of the CP by blocking activation of the C1 complement complex.[16]

Adaptive Immune Responses

T Cell–Mediated Responses

Upon antigen presentation by macrophages, dendritic cells (DCs), or B cells, naïve CD4 T cells are activated and differentiate into effector T cells. Effector CD4 T cells are classified on the basis of their cytokine production profile, which determines their mode of action and downstream effects, and include Th1 (IFN-γ-producing), T-helper [Th]2 (IL-4, IL-5, IL-13), Th17 (IL-17), or regulatory T cells (Tregs; IL-10) (Chapter 16). Interaction of *B. burgdorferi* antigen with TLRs induces the production of IL-12, which drives the differentiation of CD4 T cells into Th1 effector cells. Th1 cells are regulators of the cell-mediated inflammatory reactions, which are characterized by macrophage activation, including phagocytosis, or the induction of opsonizing IgG antibodies. Although IFNγ and Th1 CD4 T cells have been shown to be protective during cardiac inflammation with *B. burgdorferi,* joint inflammation is independent of this effector cell type in mice. However, in patients with Lyme disease, Th1 cells dominate in the synovial fluid, and the severity of arthritis directly correlates with increased levels of Th1 cells in the synovium.[17] Whether neutrophilic infiltration during joint infection with the spirochete is influenced by Th effector cells that more directly affect this cell type, such as Th17 cells (through the production of IL-17) remains to be elucidated.

B Cell–Mediated Responses

Antibodies are specific and powerful effector molecules of the adaptive immune response (Chapter 15). Once antibodies bind to their specific foreign antigen, they confer protection to the host by using a variety of effector mechanisms: antibodies contribute to adaptive immunity by neutralizing microbes or their products, activation of complement, and opsonization, which leads to phagocytosis of microorganisms. The activation of B cells and their differentiation into antibody-secreting plasma cells often requires an interaction with Th cells, and this interaction controls isotype switching as well as somatic hypermutation. However, in response to *B. burgdorferi,* T cell–independent humoral responses also confer protection to the host. Thus mice deficient in T cells, CD40L, and MHC class II infected with *B. burgdorferi* mount a protective antibody response, which, upon passive serum transfer, affords protection to severe combined immune deficient (SCID) mice from homologous challenge. However, mice that lack both B and T cells developed severe arthritis and carditis in response to infection with *B. burgdorferi.*

The role of antibodies in controlling *B. burgdorferi* infection may be more important during the hematogenous dissemination phase, when they are easily accessible, than after the spirochetes have colonized tissues. *B. burgdorferi* is able to evade the humoral response by interacting with the extracellular matrix of the mammalian host via attachment to decorin, a major component of the extracellular matrix. *B. burgdorferi* attaches to decorin with a ligand-binding lipoprotein known as *decorin-binding protein A* (DbpA). A deficiency in decorin reduces the incidence of Lyme arthritis in mice, suggesting that the interaction of DbpA with the extracellular matrix provides a protective niche for *B. burgdorferi,* preventing humoral-mediated bacterial killing. Once the spirochete is in the joints and the heart, its clearance may be more dependent on cellular responses (*e.g.,* macrophages in the heart) than on antibodies. In fact, the lack of IFNγ-mediated activation of macrophages has profound consequences on murine cardiac inflammation, even in the presence of strong antibody responses. Furthermore, the bacterial clearance potential of infected mouse sera administered in newly infected mice is lost when administered 4–8 days after infection, potentially the result of the colonization of tissues into which antibodies are less able to penetrate.

B. burgdorferi can also avoid clearance by antibodies through antigenic diversity. *B. burgdorferi* differentially expresses outer membrane antigens under pressure from the immune response, which might contribute to the ability of the spirochetes to persist in the host. A mechanism that is potentially essential for spirochetal immune escape is the recombination that takes place at the *vls* locus,[18] located near the right telomere of the linear plasmid lp28-1. *B. burgdorferi* is also able to evade antibody responses during transmission from the tick by attachment to the tick salivary protein, Salp15, which interacts with the lipoprotein, OspC, and protects the spirochete from antibody-mediated killing.[19]

HOST DEFENSES TO *T. pallidum*

KEY CONCEPTS

Protective Versus Pathological Responses to Treponema pallidum

The role of the early innate response to *T. pallidum* is still poorly understood because immunogenic cell surface proteins able to activate pattern recognition receptors remain to be found.

It is likely that the cell-mediated immune response to *T. pallidum* is involved in the development of pathology following infection with the spirochete. Likewise, this response seems to be involved in the resolution of infection with *T. pallidum.*

The protection that the humoral response affords to the host is unclear. Furthermore, no definite antigens have been isolated from the spirochete because of the inability to cultivate this organism *in vitro.*

T. pallidum is known colloquially as the "stealth pathogen" because of its denuded outer membrane, which comprises mostly nonimmunogenic transmembrane proteins, whereas the highly immunogenic lipoproteins are contained within the periplasmic space.[20] This molecular architecture, coupled with the ability to generate antigenic variants, is responsible for the treponeme's remarkable ability to cause persistent infection with relatively few organisms.[21] We have yet to elucidate many of the specific immunological phenomena that occur as a result of infection with the treponeme and that are inherent to the clinical manifestations of the disease. Our limited understanding of immunological phenomena during infection mainly results from our inability to culture these organisms *in vitro* and to reproducibly infect an animal model. Consequently, our understanding of the immune responses to this pathogen is not nearly as detailed as our knowledge of those elicited in response to infection with *B. burgdorferi.*

Innate Immune Responses

Similar to *B. burgdorferi* lipoproteins, treponemal lipoproteins appear to be the major proinflammatory agonists during treponemal infection through engagement with their cognate receptors, TLR1/2 and CD14. The inflammatory milieu established by treponemal lipoproteins is a principal driving force for immune cell recruitment to *T. pallidum*–infected tissues. The importance of this immune system compartment during the response to *T. pallidum* is further supported by the systemic upregulation of innate immune cells during treponemal dissemination and by demonstration that macrophages are principal effectors of treponemal clearance during infection.[22]

Early Pathogen Recognition

Because of their location in the skin, DCs (*i.e.,* Langerhans cells), likely mediate the initial responses to treponemes at the primary syphilitic lesion. Because of the denuded outer membrane of *T. pallidum,* extremely high treponeme to DC ratios (500 : 1 and higher) are required for observable levels of phagocytosis *in vitro.* Thus unhindered replication of spirochetes at the initial site of infection probably underlies the vigorous cell-mediated immune response, as well as chancre appearance, which follows antigen presentation to and differentiation and activation of CD4 T cells.

Phagocytic Cell Recruitment and Spirochetal Clearance

It is not until after the recruitment of macrophages and their activation via CD4 T cell–derived IFN-γ, that the majority of spirochetes are killed and resolution of syphilitic lesions occurs. Activated macrophages readily phagocytose antibody-opsonized treponemes through Fc receptor–mediated uptake. Recently, it has been shown that MyD88 mediates the opsonophagocytosis of *T. pallidum* by macrophages without affecting the production of opsonic antibodies. As result, MyD88-deficent mice infected with *T. pallidum* showed a defect in bacterial clearance that resulted in worse inflammation. These results reveal a previously unsuspected link between MyD88 signaling and FcR-mediated phagocytosis. However, as with DCs, uptake via a direct PAMP–PRR interaction does not occur readily, and because of treponemal antigenic variation, not all spirochetes will be eliminated via opsonophagocytosis despite the vigorous inflammatory response. The relatively few remaining spirochetes are able to cause persistent infection.

Complement

The immunoprotection afforded by human syphilitic serum is, in large part, a result of the activation of the complement cascade by bactericidal antibodies and spontaneous hydrolysis of C3. Thus like *B. burgdorferi, T. pallidum* activates the CP and AP of the complement cascade, and there is a considerable amount of evidence for an important role of these pathways in syphilitic lesion resolution during human infection with treponemes. In contrast to *B. burgdorferi,* there is no evidence indicating that *T. pallidum* has evolved mechanisms to evade complement-dependent killing, suggesting that these complement pathways have a larger role in controlling treponemal infection than in the case of *B. burgdorferi.*

During experimental syphilis, immunization with purified outer membrane vesicles (OMVs) isolated from *T. pallidum* results in complement-dependent bactericidal activity.[23] More recently, immunization with OMVs led to the isolation of a bactericidal monoclonal antibody (mAb), M131, which provides partial protection to experimental syphilis. M131 binds to a phosphorylcholine surface epitope of *T. pallidum* and is the first demonstration of such an antigen on the surface of the spirochete.[24]

Adaptive Immune Responses

T Cell–Mediated Responses

The infiltration of T cells (CD4 and CD8) and macrophages into the primary and secondary syphilitic lesion facilitates local clearance of the majority of treponemes and lesion resolution via a vigorous cell-mediated immune response characteristic of a delayed-type hypersensitivity or Th1 response.[25,26] CD4 T cells are the principal T-cell subset found in the lesions and are believed to promote macrophage activation and subsequent treponeme clearance through IFN-γ secretion. The role of CD8 cells is not clear, but throughout the course of primary lesion development during experimental syphilis, their proportion related to CD4 cells increases. Once the treponemes are cleared and the lesion heals, a latency stage ensues, which is characterized by long-lasting, protective T-cell memory to *T. pallidum* antigens.

B Cell–Mediated Responses

Many functional activities of human syphilitic serum originate from B-cell responses to *T. pallidum.* Infection with *T. pallidum* invokes a humoral immune response early in the course of infection, which strengthens as the number of recognizable antigens increases during the progression of infection. A polymorphic gene family of *T. pallidum, T. pallidum* repeat (*tpr*), has been recently identified as related to the major surface protein (*msp*) genes of *T. denticola.*[27] A single member of the *tpr* family, tprK, serves as an antigen for opsonizing antibodies, suggesting that this protein is a surface antigen of *T. pallidum.* However, there are only inferential indications that surface antigens of *T. pallidum* exist. So, although candidate *T. pallidum* surface proteins have been advanced on the basis of porin activity or homology with a surface protein of *T. denticola,* there is no direct evidence identifying specific surface antigens on *T. pallidum.* Furthermore, like most pathogenic organisms, *T. pallidum* has evolved various mechanisms to escape host killing. TprK is an immunogen with seven discrete variable regions differing among isolates of the spirochete.[27] In fact, the antibody response to *T. pallidum* is directed against these variable regions, which leads to immune selection of new TprK variants; thus antigenic variation is involved in the reinfection of hosts despite robust immune responses.[27,28]

Translational Research

ON THE HORIZON

- Efficient diagnostic methods that are required to rapidly identify infection and procure antimicrobial treatments
- Development of new generation vaccines for Lyme disease, including those that target the tick vector and that can prevent other tick-borne infections
- Attention to communities at risk for contracting syphilis with investments in prophylaxis and efficient treatments

The challenge in the next 5–10 years is to develop effective diagnostic methods for both Lyme disease and syphilis and to devise new preventive measures. For Lyme disease, advances in genetic manipulation, as well as other means to study structure/

function of key components of the spirochete, could lead to development of single or combination vaccines. Further, the identification of host factors that mediate a protective response and those that contribute to inflammation may result in a better understanding of the disease. Overall, the identification of the elements that mediate specific tissue tropisms for the bacterium and their interaction with local/infiltrating cellular components can permit the design of targeted therapies in conjunction with antimicrobial treatments.

A significant effort is being made to find new antigenic determinants that can be the base for a vaccine to prevent infection with *B. burgdorferi*. While the search for spirochetal antigens continue, a new wave of research has focused on finding antigenic determinants that can prevent the efficient attachment of the tick vector to the mammalian host, which, in turn, could dampen the ability of the arthropod to transmit *B. burgdorferi* and perhaps other pathogens.

For syphilis, the study of the microorganism is hampered by the difficulties associated with its culture and manipulation. Although advances have been made in our understanding of the pathology associated with infection, a significant challenge in the near future is to fully understand this pathogen. An area in which advances can be made in the next decade consists of better education of populations that are at risk of acquiring the infection. Because these populations are usually associated with low-income communities, a significant investment needs to be made to enable persons at risk to better evade the transmission of the pathogen, through education, better diagnostics, and rapid antimicrobial treatment.

CONCLUSIONS

Spirochetes are a phylogenetically ancient and distinct group of microorganisms. Because of their propensity to cause diseases in humans, *B. burgdorferi* and *T. pallidum* are the two most-well-studied spirochetes. However, the inability to culture *T. pallidum in vitro* has made researching this spirochete very difficult, and as a consequence, the immune response that follows infection with this spirochete remains poorly understood.

The etiological agents of Lyme disease and syphilis are similar in that they have relatively small genomes, surviving only in association with a host and eliciting inflammatory disease, but genomic comparison clearly shows that *T. pallidum* and *B. burgdorferi* are not closely related. It seems likely that despite some similarities, these spirochetes evolved independently from a more complex ancestor, resulting in differences in their life-cycles, environmental adaptations, and the pathology associated with their infection. Therefore it is not surprising to learn of the differences in the host immune responses to *B. burgdorferi* and *T. pallidum*. Both the host response to these spirochetes and their infectivity determine the extent of pathology following infection.

MULTIPLE-CHOICE QUESTIONS

1. The major immunogens of *Borrelia burgdorferi* and *Treponema pallidum* are:
   - **A.** Lipopolysaccharide molecules present on the outer membrane
   - **B.** Sugar coated-proteins that decorate their surface
   - **C.** A group of lipoproteins that constitute Toll-like receptor (TLR)1/TLR2 ligands
   - **D.** Both spirochetes, which are considered "stealth pathogens" because of their lack of immunogens

2. The phagocytosis of spirochetes:
   - **A.** Allows the elimination of the bacteria before they have a chance to induce a proinflammatory response
   - **B.** Allows the interaction of pathogen recognition receptors with their ligands within the phagolysosome t modulate the inflammatory response
   - **C.** Depends exclusively on the presence of opsonins that target the bacteria to professional antigen-presenting cells
   - **D.** Occurs only on tissues where the pathogens reside, exclusively upon activation of the adaptive immune system

3. The generation of a protective antibody response against *B. burgdorferi:*
   - **A.** Occurs even in the absence of T-cell responses
   - **B.** Is targeted exclusively to variable regions of the vlsE protein
   - **C.** Is always accompanied by a T-helper type 2 response
   - **D.** Occurs within the first 3 days of infection and is the basis for the successful diagnosis of patients

4. T-cell responses against *T. pallidum:*
   - **A.** Are always weak because of the low level of infection in patients
   - **B.** Induce a type I delayed hypersensitivity response that helps the elimination of the bacteria
   - **C.** Are always composed of CD4 T cells that exclusively aid the development of antibody responses
   - **D.** Can be used as diagnostic and prognostic tools for the disease

Host Defenses to Fungal Pathogens

Allison K. Lord, Jatin M. Vyas

Advances in modern medicine have significantly improved the prognosis and quality of life for patients with a wide spectrum of diseases, including many forms of cancer. However, opportunistic fungal pathogens have exploited these modern immunosuppressive and invasive medical interventions. Invasive fungal infections (IFIs) represent a significant cause of morbidity and mortality among immunocompromised patients. Patients at highest risk for IFIs include solid organ or hematopoietic stem cell transplant (HSCT) recipients on intensive immunosuppressive regimens, patients with hematological malignancies, and other patients that are immunocompromised as a result of various clinical conditions and treatments (*e.g.,* human immunodeficiency virus/acquired immunodeficiency syndrome [HIV/AIDS], advanced age, recent surgery, etc.) (Fig. 29.1).[1,2] The clinical consequences of these pathogenic fungi include superficial disease, allergic disease, and IFIs.

KEY CONCEPTS

Invasive Fungal Infections

- Invasive fungal infections are systemic life-threatening infections that are estimated to cause 1.5 million deaths annually.
- *Aspergillus, Candida, Cryptococcus,* and *Pneumocystis* are opportunistic fungi that cause the majority of invasive fungal infections.
- Risk factors for invasive fungal infections include bone marrow or solid organ transplantation, intensive immunosuppressive regimens, hematological malignancies, HIV/AIDS, advanced age, recent surgery, and other clinical conditions and treatments that cause immunosuppression.

Superficial fungal infections of the skin and nails affect 25% of the global population (≈1.7 billion people) and give rise to various conditions, including athlete's foot and ringworm of the scalp. Fungi also commonly cause mucosal infections of the oral and genital tracts; vulvovaginal candidiasis occurs at least once in 50–75% of women in their childbearing years.[3,4] Superficial fungal infections of the skin and mucosa can become chronic, but they are rarely life threatening.

IFIs occur when fungal pathogens invade the bloodstream, resulting in a systemic life-threatening infection that affects multiple organs. IFIs are estimated to cause 1.5 million deaths annually, with four genera accounting for most of the infections: *Cryptococcus, Candida, Aspergillus,* and *Pneumocystis.* Mortality resulting from infections with these fungal organisms exceeds that caused by tuberculosis or malaria.[4] As a result, IFIs have emerged as an escalating and worrisome clinical problem. There is an urgent need to define the mechanisms of host defense against fungal pathogens with the goal of developing novel therapeutics as well as improving diagnostic and preventative procedures.

One of the greatest limiting factors in the treatment of IFIs is lack of effective and prompt diagnostic tools. Although *Candida* is capable of growing in conventional blood cultures, most other invasive fungal organisms, including *Cryptococcus, Aspergillus,* and *Histoplasma*, are typically not recovered by adding blood to growth media. There has been a heavy reliance on clinical diagnosis and a few biomarkers. Fungal cell wall carbohydrates can be detected in the bloodstream of some patients. β-1,3 glucan, galactomannan, and glucuronoxylomannan (GXM) are three carbohydrates that can be analyzed clinically. β-1,3 glucan is a common fungal cell wall carbohydrate found in *Candida albicans* and many other fungi (with the notable exception of *Cryptococcus neoformans*). Galactomannan is typically associated with *Aspergillus fumigatus.* This fungal biomarker can be measured in blood and bronchoalveolar lavage fluid. GXM is an abundant fungal-derived carbohydrate produced by *C. neoformans.* GXM can also be found on the surface of *Candida gattii,* a closely related fungal organism that can cause disease in immunocompetent individuals. Although GXM appears to be a useful biomarker for *Cryptococcus,* its widespread use is limited by technical and economic issues. Finally, a urine test for histoplasmosis has been established. Again, the antigen for this test is a polysaccharide derived from the cell wall of this fungal organism. Many of these biomarkers suffer from poor sensitivity (galactomannan) and, in some cases, poor specificity (*e.g.,* testing urine for *Histoplasma* antigen).

Current therapeutic approaches for IFIs include the prompt institution of antifungal agents (including polyenes, azoles, and echinocandins) and even more important, the reversal of underlying host immune defects, such as neutropenia or high doses of immunosuppressive therapy. The first-line therapy for the treatment of invasive aspergillosis (IA) is voriconazole, an extended-spectrum azole. Despite its *in vitro* efficacy, voriconazole only demonstrated a survival rate at 12 weeks of 70.8% compared with 57.9% in the amphotericin B group.[5] Although voriconazole has become the gold standard for treatment, its high mortality rate indicates that the host immune response plays a critical role in determining host outcome. Despite clinical vigilance, prevention, diagnosis, and treatment of IFIs remain a significant challenge because of lack of rapid and reliable diagnostic methods and limited treatment options. Discovery of novel diagnostic tools and antifungal therapies is crucial to ameliorating this public health burden.

CLINICALLY RELEVANT FUNGAL ORGANISMS

Although it is estimated that there are in excess of 5 million distinct species of fungi, only a handful are considered significant to human health: *Aspergillus* spp., *Candida* spp., and *Cryptococcus* spp. cause the majority of IFIs in the United States and Europe. Invasive infections caused by these pathogens in immunocompromised patients are serious and often life threatening.

Aspergillus fumigatus

Aspergillus fumigatus is a ubiquitous airborne mold found in soil, air, food, and decaying organic material. Humans routinely inhale *A. fumigatus* conidia, but the microorganism is rapidly eliminated by the innate immune system in immunocompetent individuals. In immunocompromised patients, *A. fumigatus* can cause IA, a severe and usually fatal infection. It is estimated that IA occurs in 200 000 patients annually.[4] In cases of widespread infection, IA mortality rates approach 90%, with favorable responses to antifungal therapy observed in <30% of patients.[5] In particular, IA has emerged as a significant cause of mortality among patients who have undergone hematopoietic stem cell transplantation and solid organ transplantations. Advanced age, respiratory viruses, graft-versus-host disease (GvHD), prolonged glucocorticosteroid use, cytomegalovirus (CMV) infection, and iron overload are also common risk factors for IA.[6] Given that *A. fumigatus* spores are inhaled, IA most frequently manifests as an invasive pulmonary disease, but the pathogen can enter the bloodstream and infect multiple organs. Less frequently, IA affects skin, sinuses, and the central nervous system (CNS). Clinical characteristics of IA vary, depending on the organ(s) affected.

Aspergillus can cause a condition called *chronic pulmonary aspergillosis* (CPA), which causes progressive destruction of lung tissue. CPA is most common in patients with underlying lung disease (*e.g.,* asthma) and affects 3 million people worldwide. CPA is estimated to have 15% mortality, often as a result of a massive pulmonary hemorrhage within the first 6 months of diagnosis.[4]

Candida albicans

Candida species are ubiquitous commensal fungi that normally colonize human mucosa and skin. There are over 165 species of *Candida,* but only a few are known to cause human disease. *C. albicans* accounts for the majority of infections, followed by *C. glabrata.* Less frequently, *C. parapsilosis, C. tropicalis, C. krusei,* and others cause invasive candidiasis.[7] In immunocompromised individuals, *Candida* can become pathogenic and infect host tissues. For example, *Candida* is commonly associated with skin infections, as well as oral and vaginal thrush. However, *Candida* can become invasive (invasive candidiasis), entering the bloodstream (candidemia) and other organs (*e.g.,* bladder/kidneys, liver, spleen, gut, etc.), resulting in a life-threatening infection. Despite the availability of antifungal therapy, the crude mortality rate for candidemia exceeds 50%, indicating that the immune system is a necessary partner for successful treatment of this infection.[8] Every year, it is estimated that invasive candidiasis affects 250 000 people worldwide and causes more than 50 000 deaths.[9] As with other opportunistic fungal infections, patients on immunosuppressive regimens (*i.e.,* transplant recipients) and patients with hematological cancers are at high risk for invasive candidiasis. Other major risk factors include recent surgery, broad-spectrum antibiotic therapy, and central vascular catheters. Disruptions to the balance of *C. albicans* in the gut are associated with increasing severity of Crohn disease and ulcerative colitis (UC). Moreover, disseminated candidiasis may originate in the gut.

Cryptococcus neoformans

During the 1980s to the 1990s, cryptococcosis emerged as a major cause of morbidity and mortality among persons with HIV/AIDS. The majority of cryptococcosis cases are caused by *C. neoformans,* a fungus that is widely distributed in soil. The major route of exposure to *C. neoformans* is inhalation of airborne organisms into the lungs. In healthy individuals, the immune system is effective at clearing the pathogen, but in immunocompromised individuals (especially those with HIV/AIDS), *C. neoformans* can cause an IFI. Interestingly, *C. neoformans* targets the CNS, causing meningoencephalitis, a life-threatening condition.

HOST DEFENSE AGAINST FUNGI BY EPITHELIAL CELLS

Given the ubiquity of many fungal organisms, humans inhale a diverse species of fungi regularly. Moreover, the microbiota has a profound influence on human health. Early work on this complex collection of microorganisms focused on bacteria, but increasing evidence indicates that the mycobiome plays an important role in human health. Indeed, sequencing data from the respiratory sputum of normal volunteers showed over 40 distinct species of fungi.[10] Interestingly, sputum from patients with allergies demonstrated a distinct mycobiome. Although there is an association, it remains unclear as to whether specific species of fungi are causal for allergic responses. Growth of commensal fungi is limited by release of antimicrobial peptides and colonization by other microbial flora that compete for nutrients. Disruptions to this delicate balance can have serious pathological consequences.

Skin and the epithelial mucosa of the respiratory, gastrointestinal (GI), and genitourinary tracts represent the first line of defense against fungal pathogens, acting as a physical barrier against infection. There is evidence that epithelial cells provide more than just barrier function by triggering an immune response. Several groups have demonstrated that oral epithelial cells infected with fungi produce proinflammatory cytokines and chemokines *in vitro.*[11,12] Similarly, stimulation of human corneal epithelial cells with *A. fumigatus* hyphae activates Syk signaling and leads to production of inflammatory cytokines (interleukin-1β [IL-1β] and IL-6) and chemokines (IL-8 and CXCL1).[13] Hyphal formation is critical for inducing a strong response by epithelial cells.[14] Recently, a fungal toxin termed *candidalysin* has been identified that is a cell permeable peptide that induces a strong inflammatory response within epithelial cells. Production of candidalysin by *C. albicans* is required for T-helper 17 (Th17) responses.

C. albicans is a commensal fungus in the human GI tract, but its abundance is limited by intestinal bacteria. Antibiotics that disrupt the balance of bacterial microbiota favor overgrowth of *Candida* species. It is thought that patients with fever and neutropenia who develop invasive candidemia result from translocation of fungi from the GI tract. Emerging data connect gut homeostasis and immune responses to fungi in the lung.[15] Many questions remain about how epithelial cells discriminate fungal morphology and which proteins mediate epithelial recognition and activation in response to pathogenic fungi. Compared with host defense mechanisms exerted by myeloid cells, much less is known about host–pathogen interactions in epithelial mucosa.

THE FUNGAL CELL WALL

The fungal cell wall contains many of the relevant pathogen-associated molecular patterns (PAMPs) and epitopes for the immune response. PAMPs are recognized by cells of the host innate immune system and are often targets for antifungal agents.

The ultrastructure of fungal organisms is similar to mammalian cells. This feature has thwarted the development of a broad armamentarium of antifungal agents. However, fungi also possess a cell wall, a structure not found in mammalian cells. The fungal cell wall not only provides the organism with mechanical strength to withstand diverse environmental conditions but also maintains plasticity to permit cell growth and division and formation of different cell types throughout the life cycle of a fungal organism. Availability of nutrients, stress, hypoxia, and hypercarbia are environmental cues to the modification of the cell wall. The major constituents of the fungal cell wall are chitin, glucans, and glycoproteins. Chitin is a structurally important component of the fungal cell wall located closest to the plasma membrane. The composition of the outer layer varies, depending on the fungal species, morphotype, and growth stage. Branched β-1,3 glucan cross-links to chitin and is covalently linked to other polysaccharides (*e.g.,* galactomannan and β-1,6 glucan). The fungal cell wall composition differs dramatically between conidia and hyphae, which leads to differential recognition and response by the immune system. Many fungal species produce melanin, a natural pigment found on the cell wall and is associated with the enhanced virulence of many pathogenic fungi. Melanin protects the organism from both environmental stressors and interferes with host defense mechanisms. Specifically, fungal melanin has been associated with decreased phagocytosis, an altered cytokine response, and reduces susceptibility to antifungal drugs.[16] In some organisms, such as *A. fumigatus,* a hydrophobic rodlet layer composed of hydrophobins makes the conidia waterproof and shields underlying carbohydrates that may induce inflammation.

Fungal dimorphism is a critical feature of virulence for both yeast and molds. *C. albicans* exist in three forms that have distinct shapes: blastospores (also known as *yeast cells*), pseudohyphal cells, and true hyphal cells. Yeast cells are typically 5 μm in diameter with a round to ovoid shape. Pseudohyphae resemble elongated yeast cells that remain attached to one another. These fungi usually grow in a branching pattern that may facilitate scavenging for nutrients at distal sites. True hyphal cells are long and highly polarized, with parallel sides and no obvious constrictions between cells. Similarly, *A. fumigatus* conidia are waxy hydrophobic ovoid-shaped cells of approximately 3–5 μm in diameter. *A. fumigatus* can filament to generate hyphae that are >40 μm in length. For both *C. albicans* and *A. fumigatus,* this dimorphism is a virulence factor as organisms that fail to do so are avirulent.

THE INNATE IMMUNE RESPONSE TO FUNGAL PATHOGENS

Once a fungal pathogen has invaded the host system, innate immune cells, such as macrophages/monocytes, neutrophils, and dendritic cells (DCs), phagocytose and degrade the organism (Chapter 3). In immunocompetent individuals, physical barriers (*e.g.,* epithelial cells, mucous, skin) are effective at preventing infection. In the respiratory tract, macrophages routinely neutralize fungal pathogens that make their way to the alveoli. Understanding the rules that govern the recognition and response to these fungal pathogens provide important insights into how these organisms cause disease in immunocompromised individuals.

Recognition of fungal pathogens by innate immune cells is mediated by pattern recognition receptors (PRRs). Engagement of PRRs and PAMPs triggers a cascade of molecular events that coordinates phagocytosis and degradation of the pathogen. Additionally, release of cytokines, reactive oxygen species (ROS) production, and presentation of fungal antigens to the adaptive immune system aids in controlling infection.

KEY CONCEPTS

Innate Immunity to Fungal Pathogens

- Fungi express highly conserved pathogen-associated molecular patterns (PAMPs) that are recognized by pathogen recognition receptors (PRRs) expressed on host phagocytes.
- Dectin-1 is a C-type lectin receptor (CLR) that acts as a PRR to recognize β-1,3 glucan expressed on the cell walls of *Candida, Aspergillus,* and other fungal pathogens.
- Toll-like receptors (TLRs) recognize fungal cell wall components and nucleic acids.
- Engagement of PRRs and PAMPs initiates signaling that coordinates secretion of cytokines, reactive oxygen species (ROS) production, and presentation of fungal antigens to the adaptive immune system to facilitate elimination of the pathogen.

Recently engulfed pathogens become enclosed in membrane delineated compartments called *phagosomes,* which traffic toward the lysosome, as directed by modifications to the phagosomal membrane proteins and changes to the intraphagosomal environment. Proteins recruited to the phagosomal membrane are specific to its contents. Phagolysosomes intersect with class II major histocompatibility complex (MHC) molecules and permit loading of pathogen-specific peptides. T cells are then activated in an antigen-specific manner to augment the immune response and generate long-term immunity.

Role of Neutrophils

Neutrophils are the most critical cell in the host defense against fungal pathogens. Patients with neutropenia or acquired defects in neutrophil-mediated killing are at higher risk of developing IFIs, including IA. Although phagocytosis is a critical feature in controlling infection, other mechanisms also limit the spread of infection and serve to kill invading organisms. Neutrophils rely on multiple mechanisms for killing, including granule-dependent killing, nicotinamide adenine dinucleotide phosphate (NADPH) oxidase–dependent killing, and neutrophil extracellular trap (NET) formation (Chapter 22).

Phagocytosis of fungal organisms by neutrophils triggers production of antimicrobial ROS. Generation of ROS by the NADPH oxidase complex is a result of engagement of surface receptors, including dectin-1, and signaling adaptors, including caspase recruitment domain family member 9 (CARD9) and Syk. Loss of ROS production has a clear phenotype in *Aspergillus* infections. Patients with chronic granulomatous disease (CGD) fail to control *Aspergillus* hyphae, which leads to invasion and metastatic spread of disease. In contrast, conidial forms of *Aspergillus* do not require ROS. The data for *Candida* infections are less compelling. There appears to be modest reduction in killing of serum-opsonized *C. albicans,* but killing of unopsonized organisms is unimpaired.

In addition to cytotoxic granules and ROS production, neutrophils are capable of NET formation. This relatively newly discovered cytotoxic mechanism delivers a web-like structure composed of chromatin and histones. For *Candida,* it appears that NET formation contributes to fungal killing.[17] However, in *Aspergillus,* data from studies do not support a clear role for NETs.

Role of Macrophages

Macrophages also play a critical role in neutralizing fungal organisms. These phagocytic cells are much longer lived than neutrophils. Macrophages are recruited to the site of infection by chemotaxis. They are also responsible for patrolling interfaces with the environment, including the lung and the GI tract. In contrast to neutrophils, macrophages express class II MHC and can activate T cells. Upon activation by fungi through PRRs and PAMPs, macrophages produce potent inflammatory cytokines, including tumor necrosis factor α (TNF)-α and IL-6. Engagement of the inflammasome within these cells leads to copious production of IL-1β. Macrophages receive assistance from activated T cells that secrete interferon-γ (IFN-γ), which can activate a host of genes to improve the antifungal response from macrophages.

Role of Dendritic Cells

In contrast to macrophages, DCs can stimulate naïve T cells. Moreover, DCs are capable of taking up both yeast and conidia. DC subsets are characterized by expression of specific surface markers. Plasmacytoid DCs (pDCs) expressing specific surface markers phagocytose *A. fumigatus* conidia and spread over hyphae. pDCs incite an immune response by release of proinflammatory cytokines, including IFN-α and TNF-α. pDCs are typically found in the spleen but will migrate to the lungs following challenge by *A. fumigatus* conidia. Depletion of pDCs has been shown to result in increased mortality, indicating a nonredundant role for pDCs in host defense against *A. fumigatus.*

C. albicans epithelial infections appear to recruit pDCs. These cells reorganize and become more concentrated in the T-cell zones of lymph nodes. Draining lymph nodes of mice infected with *Candida* versus control mice showed that pDCs were the predominant DC subset after vaginal infection. pDCs are involved in the induction of Th1 responses to *C. albicans* vaginal infection.

PATTERN RECOGNITION RECEPTORS

Recognition of fungal pathogens is mediated by PRRs expressed by innate immune cells, including DCs and myeloid cells (*e.g.,* macrophages, monocytes, and neutrophils). The interaction between PRRs and PAMPs expressed on the fungal cell wall triggers downstream signaling, which elaborates the host immune response and facilitates elimination of the pathogen. The major PRRs involved in antifungal immunity are Toll-like receptors (TLRs) and C-type lectin receptors (CLRs). Other relevant PRRs include nucleotide-binding oligomerization domain (NOD)–like receptors (NLRs), and retinoic acid-inducible gene I (RIG-I)–like receptors (RLRs).

Toll-Like Receptor

Toll-like receptors (TLRs) are transmembrane receptors that recognize a broad range of microbial ligands, including fungal and bacterial cell wall components, bacterial and viral nucleic acids, and bacterial lipoproteins (Fig. 29.2) (Chapter 3). TLR1, -2, -4, -5, -6, and -10 are expressed on the cell surface, whereas TLR3, -7, -8, and -9 are expressed on intracellular membranes. Intracellular TLRs recognize nucleic acids derived from fungi, bacteria, and viruses and signal through MyD88 or TRIF. MyD88 signaling triggered by TLRs is essential for host fungal defense; mice lacking MyD88 are more susceptible to IFIs. However, humans with MyD88 signaling defects do not have increased incidence of fungal infections. To date, several TLRs have been implicated in fungal immunity in mice, including TLR2, TLR4, TLR7, and TLR9.[18] The importance of TLRs has been demonstrated in human biology. In humans, polymorphisms in TLR1, TLR3, TLR4, and TLR6 are associated with increased susceptibility to IFIs (especially IA).[19]

FIG 29.2 **Toll-Like Receptors (TLRs) and Fungal Immunity.** Surface and endosomal TLRs recognize fungal pathogen-associated molecular patterns (PAMPs) resulting in downstream signaling that promotes production of cytokines. (Adapted from Bourgeois C, Kuchler K. Fungal pathogens-a sweet and sour treat for Toll-like receptors. Front Cell Infect Microbiol 2012;2:142.)

In contrast, TLR9 polymorphisms are more tightly associated with allergic bronchopulmonary aspergillosis.

Surface-disposed TLR2 recognizes β-glucans of several fungal species (*C. albicans, A. fumigatus,* and *C. neoformans*). TLR2 also interacts with phospholipomannans and linear β-1,2-oligomannoside structures found on the cell wall of *C. albicans.* TLR2 can heterodimerize with TLR1 or TLR6 to recognize GXM, a cell wall component of *C. neoformans.* TLR2 is critical for early recruitment and the killing abilities of neutrophils.[19] TLR2-deficient mice infected with *Pneumocystis jiroveci* display more severe symptoms, increased fungal burden, and less TNF-α production.

TLR4 recognizes O-linked mannan expressed on the cell wall of *C. albicans* and through downstream signaling, stimulates production of TNF-α. Mice deficient in TLR4 do not appear to have increased susceptibility to disseminated candidiasis compared with wild-type mice. In contrast, killing of *Aspergillus* is impaired in $TLR4^{-/-}$ mice in a corneal inflammation model, although recruitment of immune cells to the infection, remains unaffected.

TLR9 recognizes intracellular microbial ligands, such as CpG-rich fungal DNA. Dectin-1–dependent Syk activation triggers phagosomal acidification, which permits cleaved TLR9 to traffic to the phagosomes. Moreover, dectin-1 regulates TLR9-dependent changes in gene expression.[20] Interestingly, TLR9 deficient macrophages have increased fungicidal activity and production of antiinflammatory cytokines. Thus TLR9 appears to modulate the inflammatory response by downregulating cytokine production.[21]

C-Type Lectin Receptor

C-type lectin receptors (CLRs) comprise a diverse family of proteins characterized by a conserved C-type lectin domain (CTLD) that recognizes a variety of ligands. CLRs that are recognized to play a role in fungal immunity include dectin-1, dectin-2, mannose receptor, Mincle, and dendritic cell–specific intercellular adhesion molecule–grabbing nonintegrin (DC-SIGN) (Fig. 29.3). However, dectin-1 is the best-characterized CLR associated with fungal immunity. Dectin-1 is a type II transmembrane protein expressed primarily on myeloid cells. It is considered the major mammalian cell surface receptor for β-1,3 glucan and β-1,6 glucan, carbohydrates widely expressed on the cell wall of many fungal organisms. Furthermore, dectin-1

promotes acidification and maturation of phagosomes.[22] Patients with mutations in dectin-1 are more susceptible to IFIs, which demonstrates the essential role of dectin-1 in mediating fungal immunity.[23]

Upon dectin-1 binding to β-1,3 glucan, a tyrosine residue within the cytoplasmic hemi–immunoreceptor tyrosine-based activation motif (ITAM) domain of dectin-1 is phosphorylated by Src family kinases, which leads to the recruitment and activation of Syk. Syk triggers the activation of the caspase recruitment domain family member 9–Bcl-10– mucosa-associated lymphoreticular tissue 1 (MALT1) complex, inducing nuclear factor (NF)-κB and production of cytokines, including IL-1β, IL-6, IL-10, IL-112, IL-23, and TNF-α. Dectin-1 can signal through a Syk-independent pathway via activation of the serine/threonine kinase, Raf-1, that phosphorylates p65, a subunit of NF-κB.[24] Cytokines produced in response to canonical (via Syk) and noncanonical (via Raf-1) NF-κB signaling are essential for the activation of Th1 and Th17 cells (Fig. 29.4).

Syk also triggers recruitment and activation of NADPH oxidase, which stimulates production of ROS, elaboration of proinflammatory cytokines, and ultimately fungal killing. Syk appears to be a master controller for phagosomal maturation and recruitment of light chain 3 (LC3), a protein associated with autophagy.

Collaboration Between TLRs and CLRs

Although most cognate ligands found on the fungal cell wall are carbohydrates that preferentially trigger CLRs, experimental evidence indicates that CLRs can collaborate with TLRs on the cell surface to coordinate cytokine production. Dectin-1 can collaborate with TLR2 and TLR4 to induce synergistically cytokines, including TNF-α, IL-10, and IL-23. This collaboration has been used clinically for management of clinical disease. *Fonsecaea pedrosoi* is the fungus that causes chromoblastomycosis, a skin infection that is difficult to treat. The CLR Mincle recognizes this pathogen. If costimulation of both CLR and TLR pathways are not engaged, the inflammatory response is defective. Exogenous administration of imiquimod, purified TLR7 ligand, facilitated pathogen clearance in mouse models and humans. This signaling requires both Syk/CARD9 and MyD88. Imiquimod is a synthetic compound with potent antiviral and antitumor activity that stimulates the innate immune system through TLR7 activation. When applied to the lesions of four patients with chromoblastomycosis, there was a rapid resolution of the infection.[25] This provides proof of concept that multiple signaling pathways are necessary for optimal activation of the innate immune system against fungal pathogens.

FIG 29.4 Dectin-1 Signaling in Response to Fungal Pathogens. Upon recognition of fungal pathogens, dectin-1 signaling triggers secretion of cytokines, production of reactive oxygen species (ROS), and activation of the adaptive immune system to facilitate elimination of the pathogen.

CARD9

Mutations in the CARD9 adaptor molecule, downstream of dectin-1, are associated with increased susceptibility to invasive *Candida* infections. Patients with CARD9 deficiencies have decreased Th17 cells, reduced chemokine/cytokine production, and impaired neutrophil activation.[26] Numerous patients have been identified to have mutations in CARD9 that lead to fungal infections. The vast majority of inborn errors in immunity that predispose to fungal disease typically also lead to development of nonfungal infections. Patients with gain-of-function (GOF) signal transducer and activator of transcription 1 (STAT1) or autosomal dominant STAT3 also suffer from mycobacterial and other bacterial infections. In contrast, mutations of CARD9 appear to affect susceptibility to fungal infections exclusively. This observation makes CARD9 a key regulator in antifungal immunity. Other genes associated with increased risk of fungal infections typically predispose patients to increased mucocutaneous or invasive disease. In contrast, CARD9 deficiency predisposes to both mucosal and systemic fungal diseases.

THE INFLAMMASOME

IL-1β activation occurs when its precursor pro–IL-1β is cleaved by caspase-1. IL-1β is critical for neutrophil recruitment and for induction of the Th17 response. Activation of the inflammasome regulates IL-1β, IL-18, IL-17, and IFN-γ. NLR family domain containing protein 3 (NLRP3) is required for activation of caspase 1. Caspase 8 may also play a role in regulating activation of IL-1β.[26] Syk-dependent production of ROS activates the NLRP3 inflammasome, which coordinates with NF-κB to promote production of IL-1β.[27] Mice lacking the inflammasome or IL-1β are highly susceptible to disseminated candidiasis.[28] In addition to ROS, lysosomal rupture, release of cathepsins, and efflux of potassium can lead to activation of the inflammasome. Many components of the fungal cell wall can trigger inflammasome activation *in vitro*. However, in these experiments, cells were pretreated with adenosine triphosphate (ATP) or lipopolysaccharide (LPS) to provide an extra signal. When whole live fungal organisms are used, pretreatment with ATP or LPS is not required.

Mice lacking NLRP3, apoptosis-associated speck-like protein containing a C-terminal caspase recruitment domain (ASC), or caspase 1 demonstrate increased susceptibility to *C. albicans* infection. The mechanism appears to be a reduction in neutrophil influx. However, in these mouse models, early neutrophil influx does not appear to be dependent on an intact inflammasome; rather, it is required for sustained neutrophil influx.

MEMORY OF INNATE IMMUNE CELLS

Historically, the innate immune response was considered a rapid and nonspecific attack against invading pathogens. The widely accepted dogma was that innate immune cells confer no immunological memory, unlike adaptive immune cells that respond more slowly but execute a specific attack based on memory. An increasing body of evidence suggests that the innate immune system can, in fact, form memory, challenging the historical dogma. For example, innate immune memory has been demonstrated in organisms that lack the adaptive immune system, such as plants and invertebrates.[29] Several studies have demonstrated increased responsiveness of innate immune cells to secondary encounters with pathogens.[30] Immunological memory of innate immune cells has been described in the context of *C. albicans* infection; in mice, preexposure to a nonlethal infection or purified β-1,3 glucan confers protection from a secondary lethal infection in the absence of functional B cells and T cells. Epigenetic modifications serve as the mechanism by which innate immune cells generate immunological memory.[31] There are numerous lingering questions about innate immune memory, including the duration of this response, its ability to provide protection from other microbes, and whether this type of response can be elicited by vaccination.

LINKING THE INNATE IMMUNE RESPONSE TO ADAPTIVE IMMUNE RESPONSE

A secondary, but critical, role of the innate immune system is to amplify the immune response by activating and recruiting cells of the adaptive immune system, including T and B lymphocytes. The innate immune signaling events that trigger activation of adaptive immunity are complex and may be pathogen dependent. This amplification of the immune response is partially achieved by secretion of cytokines and ROS that recruit immune cells to the site of infection. Additionally, antigen-presenting cells (APCs) of the innate immune system use class II MHC molecules on their surface to present pathogen-derived antigens to I CD4 T cells, resulting in differentiation into effector or regulatory T cells (Tregs).

DCs provide the critical link between the innate and adaptive arms of the immune system. DCs are capable of recognizing fungal pathogens similar to macrophages. Endowed with both TLRs and CLRs, DCs are activated by components of the fungal cell wall. Subsets of DCs provide specialized function. pDCs produce IFN-α in response to ligands that engage endosomal TLRs. Although pDCs play a key role in viral infections, their role in fungal infections is not fully understood. pDCs are able to recognize *A. fumigatus* through engagement of TLR9. When *A. fumigatus* and pDCs are coincubated *in vitro*, growth of the fungus is inhibited, indicating that these cells are capable of controlling growth of this mold. A subset of pDCs secretes IL-6 and IL-23, the latter of which can serve to prime antigen-specific Th17 lymphocytes.

$CD8^+$ DCs possess the unique capacity to cross-present antigens. Cross-presentation of *Histoplasma capsulatum* antigens has been demonstrated. Extracellular *H. capsulatum* are taken up by DCs and are then capable of triggering CD8 T cells through antigen-specific peptide-loaded class I MHC molecules.

Monocyte-derived DCs have a nonredundant role in antifungal immunity, through the induction of Th1 cells. $CCR2^{-/-}$ mice show skewed Th2 responses and poorly controlled *H. capsulatum* infection compared with wild-type control mice. Priming of Th1 lymphocytes require $CCR2^+$ monocyte-derived inflammatory DCs in mouse models of *A. fumigatus* or *C. neoformans* infection. These data indicate a critical role for DCs to connect the innate immune response to drive T-cell responses and coordinate the adaptive immune response.

THE ADAPTIVE IMMUNE RESPONSE TO FUNGAL PATHOGENS

The primary function of the adaptive immune system is to launch a highly specific attack to destroy invading pathogens. The adaptive immune system also provides long-term protection by creating “immunological memory” following an initial response to a pathogen. The two major branches of the adaptive immune system are cell-mediated immunity (CMI) and humoral immunity. B cells and T cells carry out this adaptive immune response. CMI by T cells is critical for the host response to fungal pathogens. There are two major classes of T cells that orchestrate CMI in response to invading pathogens: CD4 T cells and CD8 T cells. Antigen presentation by DCs activates T cells. T-cell activation is also driven by cytokines secreted from macrophages and DCs. In turn, activated T cells secrete cytokines that elaborate the immune response.

KEY CONCEPTS

Adaptive Immunity to Fungal Pathogens

- T-cell immunity is critical for fungal host defenses. Patient with advanced HIV infection and AIDS are at heightened risk for *C. neoformans* infection.
- T-helper 1 (Th1) and Th17 T cell subsets are the most important T cells for control of fungal infection
- Th2 cells mediate fungal asthma and hyperreactivity.
- Dectin-1 signaling is required for Th17 immunity.
- Humoral immunity may play a role in antifungal defense but appears to play a supportive role.

CD4 T Cells

CD4 T cells are major players in host fungal immunity. The critical role for CD4 T cells became overwhelmingly apparent during the AIDS epidemic. Patients with HIV/AIDS experience loss of CD4 T cells and are extremely susceptible to opportunistic fungal pathogens, especially *C. neoformans* infection. Additionally, subsets of CD4 T cells, including Th1, Th2, and Th17 cells, have specialized roles in fungal defense (Chapter 16).

Th1 Cells

Th1 cells are a subset of CD4 T cells that play a critical role in controlling fungal infections. After exposure to fungal pathogens, APCs secrete IL-12, which is critical to the maintenance and expansion of Th1 lymphocytes. Mutations in the IL-12 signaling pathway predispose mammals to *Candida, Cryptococcus,* and *Coccidiomycosis* infections. Th1 lymphocytes produce copious amounts of IFN-γ, TNF-α, and granulocyte macrophage–colony stimulating factor (GM-CSF), all of which play a critical role in antifungal defense. Although IFN-γ has multiple effects on different cell types, this cytokine induces several genes in macrophages that potently modify the distribution of proteins on the phagosome. The net result of these effects is enhanced intracellular killing. IFN-γ–treated macrophages have enhanced phagocytosis and are more efficient in antigen presentation. TNF-α has similar effects similar to those of IFN-γ and enhances the function of macrophages. Patients with mutations in the TNF-α receptor or those who are treated with TNF-α are at heightened risk for fungal infections, including *A. fumigatus.* GM-CSF appears to increase ROS production in neutrophils and macrophages. Two lines of evidence in humans suggest an important role for Th1 cells in antifungal defense. Patients with fever and neutropenia with documented IFIs, including candidemia, have improved resolution of infection independent of the effect of GM-CSF on neutrophil mobilization. Patients with protein alveolar proteinosis, which is a disease related to anti–GM-CSF autoantibodies, have increased risk of IFIs.

CLINICAL RELEVANCE

Opportunistic Fungal Pathogens Cause Invasive Fungal Infections in Immunocompromised Patients

- Advances in clinical medicine provide treatment modalities that bring new promise to once-deadly diseases. During the course of these treatments, many patients develop significant deficiencies in their immune system that permit the development of opportunistic infections.
- Invasive fungal infections (IFIs) caused by *Aspergillus fumigatus, Candida albicans,* or *Cryptococcus neoformans* are considered the most serious infections that affect immunocompromised patients. Despite effective fungicidal therapies, such as voriconazole and amphotericin, mortality in these patients exceeds 25%.
- These data indicate that a robust immune response is required for clinical efficacy. Patients with defects in innate immunity are at highest risk despite the fact that they typically have functional circulating lymphocytes.
- There is a dire clinical need to develop novel therapeutics for IFIs to address the significant public health burden caused by opportunistic fungal pathogens.

Th2 Cells

In contrast to Th1 cells, Th2 lymphocytes appear to be defense against most fungal infections. Th2 lymphocytes secrete IL-4, IL-5, and IL-13. The effects of these cytokines on macrophages diminish the antifungal response. IL-4 drives macrophage differentiation toward the alternatively activated phenotype. In mice exposed to either *Aspergillus* or *Cryptococcus* in the respiratory tract, Th2 skewing drives an allergic phenotype with airway hyperresponsiveness (AHR) and goblet hyperplasia. There is one notable exception to the deleterious effect of Th2 cells on invasive fungal disease—*P. jiroveci.* Th2 responses seem to be protective in this infection. Mouse studies suggest that alternatively activated macrophages are critical for clearance of this fungal pathogen. Recent studies have identified a nonredundant role for Th17 lymphocytes, suggesting that Th2 responses are necessary, but not sufficient, for clearance of *P. jiroveci.*

Th17 Cells

Th17 cells are a subset of CD4 T cells that have emerged as major contributors to host defense against fungal pathogens. These lymphocytes play a critical and nonredundant role in the control of IFIs. Th17 cells are characterized by production of cytokines, IL-17A, IL-17F, and IL-22. Differentiation of this T-cell lineage requires stage-specific stimulation by cytokines and activation of specific transcription factors. Transforming growth factor-β (TGF-β) and IL-6 prime the initial differentiation of CD4 T cells to Th17 cells. IL-23 is required for both maintenance and expansion of these cells.[32] Activation of STAT3 by IL-6 regulates transcription of retinoid orphan receptor-γt (ROR-γt), the master transcription factor controlling Th17 lineage commitment. Several studies have confirmed the importance of Th17 cells and IL-17/IL-23 signaling for antifungal immunity.[33] Mice deficient in IL-17 receptor fail to generate functional Th17 cells and are highly susceptible to both systemic and mucocutaneous candidiasis. Additionally, IL-23–deficient animals develop progressively worse mucocutaneous disease. Likewise, in mouse models of vulvovaginal *C. albicans* infection, impairment of Th17 cell function led to increased fungal burden. Interestingly, fungal pathogens have devised mechanisms to subvert this component of the immune system. Cell surface receptors found on *Candida* and *Aspergillus* bind IL-17 and cause increased hyphal growth and transcriptional changes within these fungal organisms that are thought to combat the immune response.

CD8 T Cells

Although CD8 T cells are critical for immune defense against viral pathogens and tumors, their contribution to fungal immunity is incompletely understood. They may provide functional redundancy to confer protection in the absence of CD4 T cells. These cells will be important in the development of fungal vaccines, but further studies are required to delineate if they have any nonredundant role in antifungal immunity.

B Cells

Early data dismissed the role of humoral immunity during fungal infection. However, clinical observations have suggested that antibodies contribute to fungal host defense. Patients with B-cell defects, including X-linked hyper-IgM syndrome and hypogammaglobulinemia, demonstrate increased susceptibility to cryptococcosis. Additionally, pediatric patients with selective IgG2 deficiency are at heightened risk for IFIs and other bacterial infections that rely on antipolysaccharide antibody formation.

Antibodies observed in normal individuals are typically against fungal cell wall components and have the capacity to inflict negative changes within the fungal cell. These include inducing transcriptional changes that are deleterious to the microbe. Antibodies can work in conjunction with complement and phagocytic cells to facilitate damage of the cell wall and trigger uptake by cells, respectively. Antibodies also have the capacity to trigger transcriptional changes that increase pathogen virulence, thereby exacerbating disease. Pleiotropic effects have made it difficult to resolve the net value of humoral immunity to IFIs.

Natural Killer Cells

Natural killer (NK) cells exert an antifungal response, but the rules that govern this response have only been elucidated recently. NK cell–mediated killing requires direct contact with the fungus, which leads to release of perforin. The NK cell receptor p30 is required for NK cell-fungal conjugate formation, pI3K signaling, and perforin release. p30 was previously identified as an activating receptor against tumor cells. In patients with

AIDS, who are highly susceptible to *C. neoformans* infection, p30 expression is decreased on NK cells leading to defective perforin release and reduced microbicidal activity. IL-12 restored p30 expression and fungal killing in a mouse model of *C. neoformans* infection by NK cells. These data indicate a direct role for NK cells against *Cryptococcus* through direct recognition by a cell surface receptor. Evidence for the role of NK cells against invasive fungal pathogens has been expanded to show that they play a nonredundant role in clearing *C. glabrata* infections. The human NK receptor p46 and its mouse orthologue natural cytotoxicity triggering receptor 1 (NCR1) bind *C. glabrata. In vitro,* NK cells lacking NCR1 show reduced capacity to kill *C. glabrata*. Indeed, NCR1$^{-/-}$ mice have increased susceptibility to *C. glabrata* infection. The ligands for p46/NCR1 are discrete members of a family of proteins called EPA (epithelial adhesion), which are glycan-binding lectins and permit attachment of fungal cells to host cells.

GENETIC SUSCEPTIBILITIES TO INVASIVE FUNGAL INFECTIONS

Although certain clinical diagnoses and medical interventions are associated with susceptibility to fungal infections, not all patients in these high-risk groups become infected. Moreover, individuals lacking traditional risk factors (*e.g.,* immunosuppression, HIV, etc.) can develop chronic or invasive fungal infections, suggesting that additional factors confer susceptibility. Primary immunodeficiencies (PIDs) include a group of hereditary immune disorders that render patients more susceptible to infection. Recent studies of PIDs have provided the opportunity to define some of the genetic and molecular mechanisms that contribute to infection. A list of genes associated with susceptibility to fungal infection are summarized in Table 29.1.

Chronic granulomatous disease (CGD) is a well-known example of a genetic disorder associated with increased susceptibility to invasive bacterial and fungal infections, especially invasive aspergillosis. CGD is caused by mutations in genes encoding subunits of the NADPH complex (*e.g., CYBA, CYBB NCF1, NCF2, NCF4*), which results in defective ROS production, a critical step in the microbial killing process.[34,35] Recent work has shown that deficiencies in ROS production resulting from a mutation in a subunit of the NADPH complex also result in defective autophagy. These defects prevent autophagy-dependent inhibition of IL-1β and increased inflammasome activation. Blocking of IL-1 protects mice with CGD from invasive aspergillosis and colitis and restores autophagic function in monocytes derived from patients with CGD.[36]

Chronic mucocutaneous candidiasis (CMC) is an immune disorder characterized by persistent or recurrent candidal infections of the skin, nails, and mucous membranes. Primarily, CMC appears to be associated with defects in IL-17 signaling. A direct role for IL-17 signaling in the protection against CMC was demonstrated in two families with deficiencies in the IL-17 receptor A (IL-17RA) and the cytokine IL-17F.[37] As mentioned previously, mutations in dectin-1 cause increased susceptibility to CMC as a result of impaired IL-1β production and a reduced frequency of Th17 cells.[38] Similarly, patients with CARD9 deficiencies have increased susceptibility to invasive fungal infections resulting from decreased Th17 cells, reduced chemokine/cytokine production, and impaired neutrophil killing.[39]

CMC is also common in patients with autoimmune polyendocrinopathy syndrome type 1 (APS-1), an autosomal recessive disorder caused by defects in the autoimmune regulator (*AIRE*) gene. In these patients, CMC results from the generation of autoantibodies against IL-17 and IL-22.[40] Hyper-IgE syndrome (HIES) is an autosomal dominant or recessive immune disorder

TABLE 29.1 Genes Associated With Immunity to Fungi in Humans

TYK2	CMC; HIES	*Candida*	Defective IL-23 signaling and reduced frequency of Th17 cells

[a] Chronic mucocutaneous candidiasis.
[b] Chronic granulomatous disease.
[c] Hyper–immunoglobulin E syndrome.

characterized by high serum IgE, eczema, and CMC. HIES is caused by mutations in multiple genes, including *STAT3, Tyk2,* and *DOCK8.*[41] Patients with *STAT3* mutations have impaired Th17 differentiation, which results in reduced number of Th17 cells and IL-17 production.[42] Autosomal dominant CMC is caused by GOF mutations in *STAT1,* which lead to decreased IL-17, IL-22, and IFN-γ production and defective Th1 and Th17 responses.[43-45] In contrast, STAT1 deficiencies confer susceptibility to viral and mycobacterial infections. *RORC* loss-of-function mutations have also been reported in humans with candidiasis; RORC isoforms ROR-γ and ROR-γT are critical for T-cell development and function.[46] Thus the absence of IL-17A/-17F–producing T cells likely accounts for the candidiasis in these patients.

The identification of genes associated with PIDs revealed several important pathways in host immunity to fungal infections. Collectively, genes associated with PIDs highlight the protective and critical role of IL-17 signaling against invasive fungal infections.

ON THE HORIZON

- The study of fungal immunology has led to a fundamental understanding of the role of C-type lectin receptors (CLRs) in immunology. Innate immunology plays a critical and nonredundant role in the defense against invasive fungal infections.
- When patients lack neutrophils or develop defects in neutrophil function, only a subset of patients develop invasive fungal infection (*e.g., A. fumigatus* infection).
- These observations suggest that genetic defects in the immune system likely contribute to increased risk of infection.
- Identification of genetic mutations that are associated with increased risk of fungal disease may permit the development of genomic risk stratification for high-risk patients.
- To this end, rational use of antifungal prophylaxis may decrease the burden of fungal disease.

SUMMARY

To date, more than 5 million distinct species of fungi have been identified, but only a few are relevant to human health. *Aspergillus* and *Cryptococcus* are ubiquitous in the environment, and their spores are routinely inhaled by humans; *Candida* spp. colonize human skin, mucosae, and GI tract and, under normal conditions, do not cause disease. Normally, the immune system is able to clear and/or limit these pathogens, but in immunocompromised individuals, these fungi can cause serious and often life-threatening infections. Using both TLRs and CLRs, the innate immune system plays a critical role in clearing the invading pathogens. Indeed, patients with defects in either innate immune cells (*e.g.,* neutropenia) or signaling through TLRs and CLRs have an increased risk for diseases caused by invasive fungal organisms. Adaptive immunity is also critical, as evidenced by patients with advanced HIV disease who are at heightened risk for *C. neoformans* disease. In general, Th1 and Th17 responses are protective, whereas Th2 responses skew the immune response to allergic and hyperactive responses.

MULTIPLE-CHOICE QUESTIONS

1. Loss of dectin-1 in patients leads to:
   A. Chronic mucocutaneous candidiasis
   B. Candidemia
   C. No clinical disease unless patient has neutropenia
   D. Increased risk of *Cryptococcus neoformans* disease

2. Which of the following carbohydrates is NOT found on the fungal cell wall?
   A. β-1,3 glucan
   B. Galactomannan
   C. Glucuronoxylomannan
   D. Peptidoglycan

3. Which T-cell response typically makes fungal infection worse?
   A. T-helper 1 (Th1)
   B. Th2
   C. Th17
   D. CD8

Host Defenses to Protozoa

Peter C. Melby, Robin Stephens, Sara M. Dann

Protozoal infections are an important cause of morbidity and mortality worldwide (Table 30.1). Protozoan pathogens exact their major toll in the tropics, but infection by these parasites remains a significant problem in developed countries because of travel to and emigration from developing countries, the susceptibility of patients with acquired immunodeficiency syndrome (AIDS) to opportunistic protozoans, and episodic transmission within communities.

KEY CONCEPTS

Host Defense Against Protozoa

- Interaction of the parasite with host cells induces an array of cytokines that stimulate the innate and adaptive immune responses to eliminate the pathogen, and/or cytokines that inhibit or downregulate the antiparasitical responses to enable the initiation of tissue parasitism.
- The outcome of infection is determined by the balance between the infection-promoting and the host-protective cytokines and effector cells. Often there is a mixed response, resulting in a persistent infection.
- A persistently infected host may develop clinical disease if there is a waning of the immune mechanisms (*e.g.,* in acquired immunodeficiency syndrome [AIDS]) that are critical to the control of infection.

Protozoan pathogens make up a group of highly diverse organisms that utilize a wide array of mechanisms for pathogenesis and immune evasion. There are numerous host targets for the intracellular protozoan parasites, including erythrocytes (*Plasmodium* and *Babesia*), macrophages (*Leishmania* and *Toxoplasma gondii*), or multiple cell types (*Trypanosoma cruzi*). The luminal parasitical protozoan may be extracellular, such as amebae and the flagellates (*Giardia* and *Trichomonas*), or primarily intracellular, such as the coccidian parasite *Cryptosporidium.*

The innate and adaptive immune systems respond in diverse ways to the blood and tissue and intestinal protozoan pathogens. Neutrophils, macrophages, and natural killer (NK) cells are the effector cells that mediate the innate response against the extracellular protozoan parasites. The NK cell–activated macrophage system is central to the innate response to intracellular parasites (Fig. 30.1) (Chapters 3, 17). The innate cytokine response activates phagocytes and is critical to the induction of the adaptive immune response via antigen presentation by dendritic cells (DCs). For the intracellular pathogens (*e.g., Leishmania* spp., *T. cruzi*, *T. gondii*), the early production of interleukin-12 (IL-12) and interferon-γ (IFN-γ) drives the differentiation of T cells to a protective T-helper 1 (Th1) phenotype. In most cases CD4 T cells play a primary role in adaptive cellular immunity, but CD8 T cells can be critically important through cytokine production (*e.g., Plasmodium* spp., *T. cruzi*, *T. gondii*) or direct cytotoxic activity (*e.g., Cryptosporidium*). For the parasites that have an extracellular stage (*e.g., Plasmodium* spp., *Trypanosoma* spp., *Giardia*, and *Trichomonas*), specific antibodies mediate acquired immunity.

Intensive effort has been dedicated to the development of effective vaccines for protozoal diseases, but as of 2016, only the malaria circumsporozoite vaccine (RTS,S) has reached the stage of clinical use. The reader is referred to a number of excellent reviews of the potential vaccine candidates.[1-4] A discussion of the immune responses to some of the individual protozoal pathogens follows.

Plasmodium spp.

Pathogenesis

Soon after *Plasmodium* spp. sporozoites are injected into the bloodstream by the *Anopheles* mosquito, they invade hepatocytes and undergo schizogony (asexual reproduction). A dormant form of *P. vivax* and *P. ovale* (hypnozoites) can reside within hepatocytes for months and then cause clinical bloodstream infection. Following schizogony, merozoites are released from hepatocytes into the bloodstream in a membrane-bound structure, known as *merosomes*. The merosomes rupture in blood, and free merozoites invade red blood cells (RBCs) to produce ring-stage parasites. These parasites mature into trophozoites, which again undergo schizogony, leading to rupture of the erythrocyte and the release of new invasive merozoites. Merozoites can also develop into sexual-stage gametocytes, which can be ingested by a feeding mosquito to continue the transmission cycle.

The clinicopathological features of malaria are caused by intraerythrocytic infection and the associated immune response. The cyclical rupture of erythrocytes is associated with fever. The induction of a proinflammatory cytokine cascade plays a central role in the pathogenesis of *P. falciparum* malaria and its complications. Parasite antigens, particularly those having glycophosphatidyl inositol (GPI) membrane anchors, released during the rupture and reinvasion of RBCs, activate the innate immune response. The production of proinflammatory cytokines (IL-1, TNF, lymphotoxin, IL-12, and IFN-γ) leads to fever, expression of endothelial adhesion molecules, and cytoadherence. It is mediated, in part, by TLR2 and is MyD88-dependent.[5] NK cells and memory T cells produce early IFN-γ, which contributes to the production of a pathologically high level of TNF. IL-10- and transforming growth factor-β (TGF-β)–mediated downregulation of the Th1 immune response and leukotriene (LT)/tumor necrosis

TABLE 30.1 Worldwide Significance of the Major Protozoal Infections

Parasite	Estimated Worldwide Cases (Annual Mortality)	Clinical Manifestations
Plasmodium spp.	400–490 million (*P. falciparum*: >2 million deaths/year, primarily children)	Fever with potential complications of severe hemolysis, renal failure, pulmonary edema, cerebral involvement
Leishmania spp.	10–50 million people infected, 1.2 million new cases per year	Asymptomatic infection; skin ulcers or nodules; destructive oropharyngeal lesions; visceral disease with fever, hepatosplenomegaly, cachexia, pancytopenia
Trypanosoma cruzi	24 million (60 000 deaths)	Asymptomatic infection; dysrhythmias or chronic heart failure; hypertrophy and dilation of the esophagus, colon
Toxoplasma gondii	Several hundred million people infected worldwide. 5–9% of healthy US adults are seropositive	Self-limited fever, hepatosplenomegaly; lymphadenopathy and encephalitis (reactivation in patients with acquired immunodeficiency syndrome [AIDS]); congenital infection, with fetal death, chorioretinitis, meningoencephalitis
Entamoeba histolytica	50 million (100 000 deaths)	Asymptomatic infection, diarrhea, dysentery, or liver abscess
Giardia lamblia	200 million (most common in young children and immunocompromised persons)	Asymptomatic infection, chronic diarrhea
Cryptosporidium parvum and *C. hominis*	Prevalence 3–10% in patients with diarrhea in developing countries	Self-limited diarrhea in immunocompetent persons, severe intestinal and biliary disease in patients with AIDS
Trichomonas vaginalis	170 million/year	Asymptomatic infection, vaginal discharge, urethritis

FIG 30.1 **Macrophage, Natural Killer (NK) Cell, and Cytokine Interactions in the Innate Immune Response to Intracellular Protozoa.** Exposure of macrophages or dendritic cells to a pathogen or microbial product can result in the release of cytokines and inflammatory mediators that may stimulate (+) or suppress (–) NK cell activation. Activated NK cells produce cytokines that can then activate macrophages for intracellular killing. It must be recognized that this diagram is oversimplified and that these cytokines, most notably interferon (IFN)-α/β, interleukin (IL)-10, transforming growth factor (TGF)-β, and IL-12, may be produced by other types of cells, such as epithelial cells or enterocytes. NO, nitric oxide; RNI, reactive nitrogen intermediates; ROI, reactive oxygen intermediates.

factor (TNF) production, which have a role in severe and cerebral malaria, act to limit the inflammatory response.

Severe malaria includes severe anemia, respiratory distress, placental malaria, and cerebral malaria, with the latter causing up to 90% of deaths. In cerebral malaria, a combination of inflammation, cytoadhesion of parasites, and leukocytes, and vascular pathology leads to coma. Cytokines and endothelial cell production of nitric oxide (NO) contribute to inflammatory lesions in the brain. Patients may die as a result of severe edema and swelling of the brainstem. Severe anemia is the result of a combination of destruction of infected and uninfected RBCs and dyserythropoiesis. Both destruction of uninfected RBCs and malformation of RBCs in bone marrow are increased by inflammatory cytokines, as is the damage in placental malaria.

KEY CONCEPTS

Immunopathogenesis of Severe Plasmodium falciparum *Malaria*

- Release of malarial antigens stimulates tumor necrosis factor (TNF), interleukin (IL)-1, and lymphotoxin production from innate immune cells.
- TNF/leukotriene (LT) induce vascular leakage, hemorrhage, endothelial cell activation with expression of endothelial adhesion molecules, platelet activation and adhesion, and coagulation.
- Inflammatory cytokines amplify severe anemia caused by loss of infected red blood cells (RBCs) by inducing dyserythropoiesis and phagocytosis of uninfected RBCs, which can be coated with parasite antigens.
- Lethal outcomes for the fetus of infected women during pregnancy are caused by the local immune response induced by placenta-specific parasites.

Innate Immunity

Complement-mediated lysis can occur at the sporozoite and merozoite stages, though parasites have evolved evasive mechanisms. While sporozoites rapidly transit from the skin to the liver, they can activate DCs at the site of inoculation or in the regional lymph node. Early activation of NK cells and IFN-γ are associated with better outcomes of infection. Although high levels of TNF are associated with severe malaria, physiological levels are protective through the activation of macrophages. γδ T-cell receptor (TCR)$^+$ T cells that respond to phosphorylated nonpeptide antigens on live parasites have been demonstrated. DCs initially induce a strong adaptive immune response to the erythrocytic stage, which is tempered during prolonged infection.

Adaptive Immunity

Partial immunity to *Plasmodium* spp. infection is acquired slowly following repeated exposure in endemic areas.[6] In areas of intense perennial *P. falciparum* transmission, the density of parasitemia, morbidity, and the incidence of cerebral malaria and malaria-related deaths are highest in the early childhood years, declining thereafter. Naturally acquired immunity to repeated infections develops in young adults, with the exception of the morbidity associated with placental infections.

Adaptive immunity to the preerythrocytic stage is primarily mediated through major histocompatibility complex (MHC) class I-restricted parasite-specific CD8 T cells and, to a lesser extent, CD4 T cells, via IFN-γ-induced NO-dependent killing of intrahepatocyte parasites.[7] Potentially protective immune mechanisms against the preerythrocytic stage have largely been identified by study of mice vaccinated with irradiated sporozoites and challenged with murine *Plasmodium* spp. Irradiated sporozoite challenge also protects humans and is being scaled up for vaccine trials. Antisporozoite immunity requires the presence of high antibody titers and high numbers of T cells to block sporozoite invasion of the hepatocyte, which occurs in just a few cells within minutes of inoculation.

Both antibody-dependent and cell-mediated immune mechanisms are active against the erythrocytic stage of infection. Both B cells and CD4 T cells are required for complete clearance of parasites.[8] Adoptive transfer of human immune serum is protective for naïve individuals. Antibodies directed against merozoite surface proteins can inhibit invasion. A significant proportion of antibodies to infected erythrocytes are directed toward variant antigens, such as PfEMP-1 on the surface of the RBC. Immunoglobulin G1 (IgG1) and IgG3 isotype antibodies specific for parasite antigens exported to the surface of the RBC play a role in naturally acquired immunity by opsonizing infected cells for phagocytosis in the spleen.

CD4 T cells are implicated in protection by experiments showing that MHC class II–restricted antigen presentation is required for reduction of parasitemia and pathology. Protective cellular immune responses (CD4 and CD8 T-cell proliferation, IFN-γ production, and NO synthesis) in the absence of detectable antibody responses were identified in naïve volunteers, who were protected by repeated exposure to low doses of blood-stage parasites. In addition to promoting phagocytosis, CD4 T cells are required to help B cells, especially by the production of IL-21. One of the most important roles for CD4 T cells is the regulation of the intense inflammatory response through production of antiinflammatory cytokines IL-10 and TGF-β.

Evasion of Host Immunity

The malaria parasite uses several different mechanisms to evade the host immune response.[9,10] Sporozoites and merozoites evade circulating antibody by rapidly entering hepatocytes or RBCs, respectively. Some sporozoite proteins enter the hepatocyte nucleus and influence the expression of a number of host genes, thereby favoring parasite survival. Mature RBCs do not express MHC molecules on their surface and so avoid recognition by T cells. The few parasite proteins that are expressed on the erythrocyte surface exist in multiple allelic forms to avoid quick recognition by the adaptive immune system. Many of the immunodominant antigens in *Plasmodium* spp. are proteins having extensive repeat sequences that vary over time. The large number of bloodborne antigens induces a plasmablast response generating a short-lived burst of low-affinity antibodies. Although there is an increase in atypical B cells, memory B cells and long-lived plasma cells are generated. It is unclear if poor immunity following a single infection is caused by ineffective, atypical B cells or misdirected antibody specificity.

Leishmania spp.

Pathogenesis

The intracellular *Leishmania* amastigote replicates within macrophages in the vertebrate host, and the extracellular promastigote develops within the insect vector. The female phlebotomine sand fly becomes infected by ingesting amastigotes during a blood meal. In the sand fly gut, the amastigotes differentiate into infectious metacyclic promastigotes that infect the vertebrate host during the next blood meal. The surface lipophosphoglycan (LPG) plays a central role in the parasite's entry and survival in host cells. Immunomodulatory factors present in the sand fly saliva may enhance the infectivity of the parasite. Once introduced into skin, the promastigotes are phagocytosed (through complement–complement receptor–mediated coiling phagocytosis) by neutrophils, DCs, and macrophages, where they transform to amastigotes and replicate within the acidic and hostile environment of the phagolysosome. Eventually, the phagocytes rupture and release amastigotes to infect other macrophages or a sand fly.

Innate Immunity

Much of what we know of immunity in leishmaniasis comes from studies of inbred mouse strains, which demonstrate a genetically determined spectrum of innate and adaptive immune responses that shape the outcome of infection. The innate immune response to *Leishmania* is mediated by complement, NK cells, cytokines, and phagocytes.[11] The production of IL-12 early in the course of infection by DCs leads to the early activation of NK cells and the production of IFN-γ. Chemokines (IP-10, MCP-1, and lymphotactin), as well as LPG–TLR interaction, can also promote the early NK-cell activation. Activated NK cells have been shown to be cytolytic for *Leishmania*-infected macrophages, but NK cell–derived IFN-γ plays a more prominent role in host defense by activating macrophages to kill the intracellular parasite through the generation of reactive oxygen intermediates (ROIs) or reactive nitrogen intermediates (RNIs). Parasite-induced, MyD88-dependent signaling through TLR2, TLR3, and TLR4 contributes to macrophage activation and NO production. Activated polymorphonuclear leukocytes (PMNs) can kill parasites through oxidative mechanisms, but the role of neutrophils *in vivo* depends on the timing of their recruitment and their interaction with other immune cells.[12] An important study demonstrated that infiltrating neutrophils promote sand fly–transmitted infection, probably through modulation of macrophage function following engulfment of apoptotic parasitized neutrophils.[13] Type 1 IFNs participate in the early induction of NO and control of parasite replication early in infection.

Adaptive Immunity

Within an endemic area there is acquisition of immunity in the population over time. Retrospective epidemiological studies indicate that most individuals with prior (primary) infection (subclinical or healed) are immune to a subsequent clinical infection. Following primary infection, parasites persist for the life of the host and maintain long-term immunity.

There is extensive evidence from experimental models that cellular immune mechanisms mediate adaptive resistance to *Leishmania* infection, and human studies have generally confirmed this. Antileishmanial antibodies, which are produced at a low level in localized cutaneous leishmaniasis (LCL) and at a very high level in visceral leishmaniasis (VL), play no role in protection. The general mechanisms of cellular immunity in leishmaniasis can be summarized (Fig. 30.2). Following infection in the skin, migratory dermal DCs phagocytose *Leishmania* and presumably transport the intracellular parasite to the regional lymph node, where they induce a T-cell response. Adaptive immunity is primarily mediated by parasite-induced production of IFN-γ by CD4

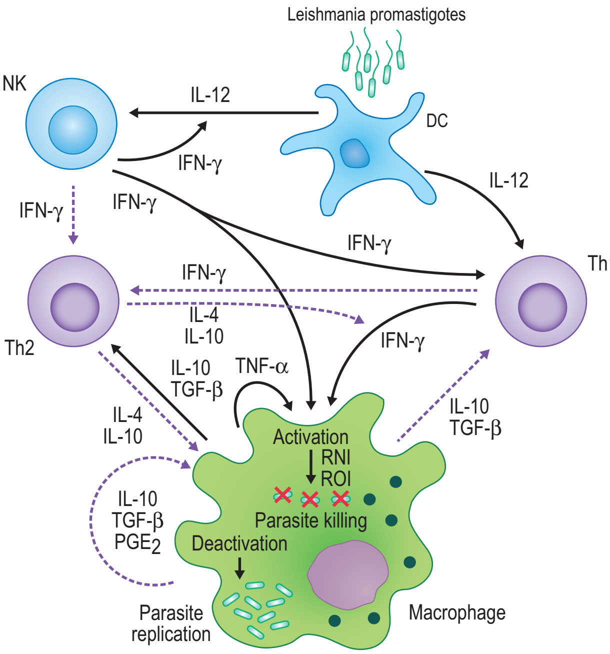

FIG 30.2 Immunity in Leishmaniasis. Exposure of dendritic cells to parasites or parasite antigens leads to the release of interleukin (IL)-12, which induces natural killer (NK) cells to produce interferon (IFN)-γ and drives the adaptive immune response toward a protective T-helper 1 (Th1) phenotype. IL-12 production by dendritic cells and IFN-γ production by NK and Th1 cells negatively regulates the Th2 response. IFN-γ activates macrophages to kill the intracellular pathogen. In genetically susceptible individuals, a counterregulatory Th2 cytokine response can suppress the Th1 response and impair classic macrophage activation, leading to parasite replication and uncontrolled infection. Counterprotective macrophage-derived cytokines can also inhibit the Th1 response, stimulate the Th2 response, and impair classical activation through an autocrine loop. Activating stimuli are shown by solid arrows, and deactivating stimuli are shown by dashed arrows.

T cells (Th1 subset). CD4 T cells are absolutely required, but immunity to cutaneous disease is also mediated by CD8 T cells via production of IFN-γ.[14] Both CD4 and CD8 T cells are required for an effective defense against murine visceral *L. donovani* infection, but the precise role of CD8 T cells is unclear. The generation of the Th1 response is critically dependent on CD40-CD40L-mediated IL-12 production and driven by NK cell–derived IFN-γ. IL-12 and STAT4 are required for the maintenance of immunity. Tumor necrosis factor-α (TNF-α) contributes to protective immunity by synergizing with IFN-γ to activate macrophages. Recently nuclear factor-kappa B (NF-κB) family members have been shown to regulate T-cell responses and immunity to *L. major* infection in mice.

Two subpopulations of CD4 T cells mediate immunity induced by primary infection. Effector memory cells, which are short-lived and dependent on the persistence of antigen, rapidly respond to secondary infection by migrating to the infected tissue and generating effector cytokines. Central memory T (T_{cm}) cells, which can be maintained in the absence of persistent antigen, circulate throughout the lymphatic system and upon secondary challenge migrate to and proliferate in the draining lymph node, gain the capacity to produce IFN-γ, and then migrate to the site of infection. Thus T_{cm} cells act as a reserve of antigen-reactive T cells that can expand and become effector T cells in response to secondary antigenic challenge.

The generation of RNI by activated macrophages is the primary mechanism of parasite killing in the murine model. Although IFN-γ-induced production of NO may not be detectable in human macrophages, inhibition of nitric oxide synthase 2 (NOS2) was shown to impair killing of intracellular *Leishmania*.

Several adaptive immune mechanisms promote parasite replication and disease.[15] The progression of murine *L. major* infection has been correlated with the expansion of Th2 cells and the production of IL-4, IL-5, and IL-10. In susceptible mice, IL-4 production within the first day of infection was shown to downregulate IL-12 receptor β-chain expression and drive the response to a Th2 phenotype. However, other nonsusceptible mouse strains appear to be able to overcome an early IL-4 response and develop a resistant phenotype, and susceptibility to some *L. major* strains is not strictly mediated by IL-4 (IL-13 and/or IL-10 may have a prominent role). The cytotoxic activity of CD8 T cells may promote cutaneous inflammation and lesion pathology.[14] The macrophage production of immune suppressive molecules, such as TGF-β or prostaglandin E_2 (PGE_2), may also contribute to susceptibility.

Peripheral blood mononuclear cells (PBMCs) isolated from patients with localized cutaneous leishmaniasis demonstrate a Th1 response to *Leishmania* antigens, and in the cutaneous lesion, there is an exuberant Th1 and granulomatous response that mediates parasite killing and localized tissue damage, which usually leads to a scar. Patients with mucosal leishmaniasis (ML) exhibit vigorous cellular immune responses characterized by high levels of TNF-α and Th1 and Th17 cytokines; it is postulated that this hyperresponsive state contributes to the prominent tissue destruction of ML. Patients with diffuse cutaneous leishmaniasis (DCL) resemble the progressive infection caused by *L. major* in BALB/c mice in that there are minimal or absent *Leishmania*-specific lymphoproliferative responses, and predominant Th2 cytokine expression. During active VL in humans, there is a marked depression of *Leishmania*-specific lymphoproliferative and IFN-γ responses, contraction of circulating memory T cells, and an absence of delayed-type hypersensitivity (DTH) response to parasite antigens. This T-cell unresponsiveness appears to be mediated, at least in part, by a suppressive effect of IL-10 and low levels of IL-12. Successful treatment of active disease restores an antigen-specific Th1 response.

Evasion of Host Immunity

The *Leishmania* parasite has numerous ways in which it adapts to and survives within the vertebrate host.[16] In skin, the promastigotes may be phagocytosed by neutrophils and macrophages, which, unlike DCs, do not actively participate in T-cell priming. Furthermore, the clearance of apoptotic neutrophils is likely to make macrophages more permissive to infection.[13] The parasite's surface LPG (and, to a lesser extent, the surface protein gp63) plays an important role in the entry and survival of *Leishmania* in the mammalian host by conferring complement resistance and by facilitating the entry of complement-opsonized parasites into the macrophage without triggering a respiratory burst. Macrophage phagosome–endosome fusion and phagolysosomal biogenesis are also inhibited by parasite LPG.

Leishmania-infected macrophages have diminished capacity to initiate and respond to a T-cell response, and the impaired

TABLE 30.2 Evidence for Autoimmune and Parasite-Induced Inflammatory Mechanisms in Chronic Chagas Disease

Evidence for Autoimmune-Mediated Disease	Evidence for Parasite-Induced Inflammatory Disease
Inflammatory disease presents in tissues with few or no parasites on routine histopathology studies	Sensitive parasite detection techniques (polymerase chain reaction [PCR], immunohistochemistry) correlate with the presence of parasites (or parasite material) and severity of inflammatory disease
Peculiar pattern of organ involvement (heart and gastrointestinal tract) in patients with chronic disease	Organs free of parasites (by sensitive parasite detection techniques) are also free of disease
Long delay in the onset of chronic disease following infection; only a minority of infected persons develops disease	Absence of effective cellular immune response (in mice or humans) almost invariably exacerbates rather than reduces the parasite burden and disease
Wide variability in the expression of disease among infected people	In chronically infected mice, the destruction of a transplanted heart is dependent on parasite infiltrating the transplanted tissue
Self-reactive antibodies and T cells demonstrable in infected people and in experimental animals. Level of antibodies to the ribosomal P protein (R13 peptide) and cardiac myosin (B13 antigen) correlate with cardiac disease	Degree of disease in hearts transplanted into chronically infected mice correlates with level of parasite burden in transplanted tissue
Transient or limited disease reported in experimental models following lymphocyte transfer	Reduction of parasite burden by chemotherapy usually leads to decreased tissue inflammation and disease

antimicrobial effector activity provides a safe haven for the intracellular parasite.[16] Infected macrophages have decreased synthesis of IL-1 and IL-12, and blunted IFN-γ-mediated activation through the disruption of signal transduction pathways involving JAK/STAT, protein kinase C, p38 MAPK, ERK, AP-1, and NF-κB. Signaling mediated by tyrosine phosphorylation is decreased by the rapid induction of the host phosphotyrosine phosphatase SHP-1. Conversely, there is increased synthesis of the immunosuppressive molecules IL-10, TGF-β, and PGE_2. Parasite factors and IL-4/IL-13 enhance expression of arginase by infected macrophages. Arginase promotes infection through depletion of L-arginine, enhanced production of polyamines, and reduced NO production. IL-10 produced by $CD4^+CD25^+$ T regulatory cells (Tregs) has an essential role in parasite persistence. Recently, it was shown that metastasizing parasites that cause mucosal disease harbor a high burden of *Leishmania* RNA virus, which subverts the host immune response and promotes parasite persistence through activation of Toll-like receptor 3 (TLR3).[17]

Trypanosoma cruzi

Pathogenesis

T. cruzi is transmitted to the mammalian host when the infectious metacyclic trypomastigote, which is deposited on skin in the feces of the reduviid insect vector while it takes a blood meal, is scratched into the wound or transferred to a mucous membrane (*e.g.*, the eyes). The trypomastigotes can infect almost any cell type and replicate as amastigotes in the cytoplasm. Eventually, the amastigotes transform back into trypomastigotes and rupture the cell to enter the bloodstream, from where they invade other cells or are picked up by another insect vector.

Following primary infection, the parasites replicate locally and then disseminate through the bloodstream to a variety of tissues. Muscle and glial cells are the most frequently infected cells, and acute myocarditis or meningoencephalitis can develop. In most cases, however, primary infection occurs without clinical symptoms, and the infected individual may enter an indeterminate phase of asymptomatic seropositivity. Only 10–30% of chronically infected individuals will ultimately develop symptomatic Chagas disease, usually involving the heart or the gastrointestinal (GI) tract. Pathologically, there are few parasites observed in cardiac tissue, but an intense chronic inflammatory infiltrate with fibrosis and loss of muscle fibers is evident. In the digestive tract, there is lymphohistiocytic infiltration of the myenteric plexuses, with reduction in the number of ganglion cells.

The tissue damage of acute *T. cruzi* infection is the result of a direct effect of the parasite and an indirect effect of the acute inflammatory response. In chronic infection, the balance between immune-mediated parasite containment and host-damaging inflammation determines the course of disease. The pathological mechanisms related to chronic Chagas disease are controversial and certain to be multifactorial. Trypanosomal clonal variation and host genetic polymorphisms both contribute to tissue tropism, parasite persistence, and disease severity. Whether tissue damage is caused directly by parasites or indirectly through parasite-driven inflammatory or autoimmune mechanisms, parasite persistence is a significant driver of disease (Table 30.2).[18,19] Autoimmunity could arise from molecular mimicry of self by parasite antigens or by the release of self molecules from damaged or dying host cells within the environment of an activated immune response. There is evidence for both of these autoimmune mechanisms. The production of IL-10 by *T. cruzi*–infected cells may downregulate the pathological cellular immune response.

Innate Immunity

The early innate immune response to *T. cruzi* infection is mediated by NK cells, DCs, and macrophages.[20] Macrophages and DCs exposed to *T. cruzi* trypomastigote antigens produce IL-12 and TNF, through a MyD88-dependent mechanism. MyD88-deficient mice had impaired inflammatory responses and host defense against *T. cruzi*. Immune activation through another protein involved in TLR2 signaling, the Toll/IL1R domain-containing adapter protein– inducing IFN-β (TRIF), promotes resistance through production of IFN-β and downstream expression of IFN-β inducible genes, such as the p47 guanosine triphosphatases (GTPase) *IRG47*. IL-12 activates NK cells to secrete IFN-γ, which synergizes with TNF to activate macrophages to control parasite replication. The generation of NO is the primary trypanocidal mechanism in murine macrophages. A number of trypomastigote antigens, including free glycosyl-phosphatidylinositol (GPI) anchors, glycoinositol phospholipids (GIPLs), GPI-linked glycoproteins, and GPI-mucins activate the innate immune response, in part through TLR2 and possibly TLR4. CpG motifs in the *T. cruzi* genome have also been shown to activate TLR9. Several other TLR-independent mechanisms of innate immunity, including the activation of nucleotide-binding oligomerization domain (NOD)–like receptors, have been identified.[20]

Adaptive Immunity

The innate immune response, through production of IL-12, type I IFNS, and other proinflammatory mediators, is critically linked to the generation of an effective adaptive immune response. Antibodies contribute to immunity within the bloodstream through opsonization, complement activation, and antibody-dependent cellular cytotoxicity.

Several lines of evidence establish the importance of T cells in adaptive immunity to *T. cruzi* infection. Parasite-specific CD4 and CD8 T cells are activated during infection, and mice lacking CD4 or CD8 T cells have impaired parasite control. CD8 T cells with cytotoxic activity against *T. cruzi*–infected cells have been identified in infected mice, and these cells confer protection when passively transferred to naïve mice.[21] In the early stage of infection, CD4 T cells are the predominant subset recruited to the myocardium, but activated CD8 T cells soon dominate the inflammatory process in cardiac tissue. IFN-γ and TNF production by parasite-specific CD8 T cells is more important than cytolytic activity in the control of infection.[21]

T. cruzi infection leads to a mixed Th1/Th2 cytokine response, and in general, the Th1/Th2 balance determines resistance or susceptibility. As noted earlier, IL-12/STAT4-dependent IFN-γ production by NK cells in early infection, and later by T cells, is critically important to protection. IL-4 does not appear to play a major role in susceptibility to *T. cruzi* infection, but IL-10 promotes parasite replication by inhibiting macrophage trypanocidal activity. IL-10 also plays a critical role in minimizing inflammation-mediated tissue pathology by regulating the Th1 and TNF responses. Polymorphisms in the IL-10 gene that lead to reduced IL-10 production are associated with increased severity of cardiomyopathy in patients with Chagas disease. Similarly, TGF-β has been shown to inhibit macrophage trypanocidal activity and increase parasitemia and mortality. In addition to these regulatory cytokines, the secretion of prostaglandins and NO, the induction of apoptosis of T and B cells, and the expansion of a myeloid suppressor cell population serve to control the intensity of the immune response.

Evasion of Host Immunity

A significant part of the pathogenesis following *T. cruzi* infection is its dissemination through the bloodstream to many tissues. *T. cruzi* bloodstream trypomastigotes resist complement lysis via a complement regulatory protein (GP-160). This parasite protein is functionally similar to mammalian decay-accelerating factor in that it inhibits C3 convertase formation and activation of the alternate complement pathway. *T. cruzi* invades host cells, in particular cardiomyocytes, by subverting a host plasma membrane repair pathway that promotes parasite persistence and tissue tropism.[22]

The establishment of chronic infection by *T. cruzi* is favored by a generalized depression of T-cell responses. A number of different mechanisms may contribute to this, including low IL-2 production or IL-2 receptor expression; downregulation of components of the T cell–receptor complex; T-cell receptor dysfunction; apoptosis of T cells; defects in the processing and presenting of antigens in the MHC class II (but not the class I) pathway, T-cell or macrophage suppressor activity, and PGE_2 production. Within the foci of myocarditis, apoptosis of both parasites and host cells occurs. The phagocytosis of these apoptotic cells by macrophages leads to their acquisition of an M2 phenotype, which enables parasite replication and persistence. The rapid escape of the parasite from the phagosome into the cytoplasm through the action of acid-activated porins enables the organism to avoid phagolysosomal enzymatic destruction.

Toxoplasma gondii

Pathogenesis

Transmission occurs via the ingestion of oocysts, which are shed in the feces of felines or via tissue cysts present in undercooked meat. Following the oral ingestion of cysts, phagocytes recruited to the gut lumen facilitate transepithelial migration into the lamina propria. These phagocytes have been termed "Trojan Horses," as they carry the parasite to new, unsuspecting host cells. Host-cell invasion starts with loose attachment facilitated by laminin. Intracellular tachyzoites replicate within a parasitophorous vacuole (PV) and ultimately leave the cell by using an active egress pathway. The released tachyzoites can disseminate to invade virtually any nucleated cell type, but mononuclear phagocytes are the preferred host cells. The toxoplasma SAG proteins mediate parasite attachment, and the transmembrane adhesins, MIC and AMA1, and RON family proteases play major roles in the myosin motor-driven process of host-cell invasion. Under pressure from the host immune response, tachyzoite replication is controlled and tissue cysts, containing slowly replicating bradyzoites, are formed. The tissue cysts persist as a chronic latent infection as long as the host immune function is intact. If the latently infected person is immunosuppressed, reactivation occurs, and tachyzoites are released to infect more cells. Because tissue cysts (bradyzoites) are found in proportionately larger numbers in the brain, reactivation of latent infection in the immunocompromised host most commonly manifests as encephalitis.

Innate Immunity

Similar to immunity to *Plasmodium* and *Leishmania,* IL-12, IFN-γ, TNF-α, and NK cells contribute to the control of the early stages of *T. gondii* infection.[23] $CD8\alpha^+$ DCs are the primary producers of IL-12, which is essential to host resistance. IL-12 is produced through a MyD88-dependent mechanism, at least in part, through the interaction of parasite-derived proteins and TLR2 and TLR11, and activation of CCR5.[24] IL-12-dependent activation of NK cells leads to IFN-γ production, which, in turn, activates macrophages to limit parasite replication. T cells expressing the γδ receptor and neutrophils are also an early source of IFN-γ and TNF-α. Recruitment of inflammatory macrophages to the site of infection is crucial to control of parasite replication and dissemination. IFN-γ-induced macrophage activation is the key effector mechanism leading to parasite killing. In mice, the induction of immunity-related GTPases (IRG), which damage the parasitophorous vacuole membrane and kill *T. gondii* within the cytosol, is the primary macrophage effector mechanism. The generation of reactive nitrogen and oxygen intermediates, degradation of tryptophan, and the production of LTs have also been implicated in the control of *T. gondii* in human macrophages. However, humans lack the entire IRG family, as well as TLR11, and the mechanism(s) of early IFN-γ–mediated macrophage activation and parasite control in humans is unclear.

Adaptive Immunity

Although serum antibodies can be used in the diagnosis of *T. gondii* infection, the systemic antibody response does not play a role in adaptive immunity. Mucosal IgA, however, does provide resistance to oral infection with *T. gondii* cysts. CD4 and CD8 T cells are highly activated during infection and are essential for adaptive immunity. As such, patients with defects in T cell–mediated immune responses (*e.g.*, patients with AIDS) are at risk for reactivation of latent infection.

IL-12 from DCs drives the differentiation of T cells into type-1 CD4 and CD8 T cells that are essential to adaptive immunity. CD4 and CD8 T cells act synergistically to prevent cyst reactivation during chronic latent infection. Parasite-specific cytolytic T cells have been demonstrated; however, CD8 T cells mediate protection primarily through the generation of IFN-γ. IL-12 drives the generation of terminally differentiated CD8 effector T cells, which express the killer cell lectin-like receptor G1 (KLRG1) and high levels of granzyme B and IFN-γ. The combination of IL-7 and IL-15 is required for T_{cm}-cell differentiation.

Antiinflammatory molecules, particularly IL-10 and IL-27 made by Th1 cells, play an important role in modulating the adaptive immune response and restricting host tissue damage.[25]

Evasion of Host Immunity

T. gondii escapes early macrophage killing in a number of ways.[25] Virulent parasites are protected by localization to the parasitophorous vacuole, which does not fuse with host cell lysosomes (probably because the PV membrane proteins are of parasite rather than host origin), and so the vacuole is not acidified to kill the parasite. The infected macrophage is also a suboptimal target for T cell–induced immunity because of reduced expression of MHC class II and costimulatory molecules. Infection also induces the production of counterregulatory molecules, such as IL-10, TGF-β, lipoxin A4. These not only downregulate a potentially pathological host inflammatory response but also inhibit Th1 induction and macrophage antimicrobial activity. In addition, *T. gondii* interferes with normal macrophage signaling. For example, infection inhibits DNA binding of signal transducer and activator of transcription 1 (STAT1) and NF-κB by interfering with chromatin structure, and promotes antiinflammatory pathways downstream of the suppressor of cytokine synthesis proteins. The parasite also has several virulence proteins, including ROP5 and ROP16, which bind to the parasitophorous vacuole and reduce accumulation of the IRGs. ROP proteins also activate host STAT3 and STAT6 driving an M2 macrophage phenotype that is permissive to infection.[26]

Entamoeba histolytica

Pathogenesis

E. histolytica causes asymptomatic intestinal colonization, acute diarrhea, dysentery, colitis, liver abscess, and, rarely, disseminated disease. Susceptibility to amebiasis is determined by the host's nutritional status, intestinal microflora, genetics, and gender.[27] *E. histolytica* cysts are ingested through consumption of food or water contaminated by feces. After excystation, the trophozoites degrade the colonic mucus barrier through secretion of proteases and glycosidases. The trophozoites adhere to the colonic epithelial cells by a galactose/*N*-acetylgalactosamine-inhibitable lectin (Gal/GalNAc), which leads to NF-κB activation and proinflammatory cytokine release. Epithelial cells with adherent amebae undergo microvilli shortening and apical separation that allows the parasite to penetrate between the epithelial cells and degrade connective tissue, resulting in ulceration of the mucosa and submucosa (Fig. 30.3). The trophozoites can lyse multiple cell types, including neutrophils, which release enzymes that further damage the tissue. The cytotoxic effects of amebae are mediated by a secreted cysteine protease, the Gal/GalNAc lectin, phospholipase A, and contact-dependent cytolysis, in which an ion channel (amebapore) is inserted into the membrane of target cells. *E. histolytica* can induce apoptosis in mammalian cells by a caspase-dependent, TNF-α/Fas–independent process. Amebic liver abscesses develop when trophozoites erode through the intestinal submucosa, enter the portal circulation, and disseminate to the liver.[28] Comparison of the transcriptional profiles of virulent and nonvirulent *Entamoeba* species has identified novel virulence factors in *E. histolytica.*[29]

Innate Immunity

Adherence of trophozoites to intestinal epithelial cells stimulates the release of a variety of proinflammatory mediators, including IL-1α, IL-1β, IL 6, IL-8, and TNF-α, which triggers the recruitment of neutrophils and macrophages to the site of invasion. Following activation by IFN-γ and TNF-α, neutrophils and macrophages become amebicidal through the release of reactive oxygen species and production of nitric oxide, respectively.[28] Invariant natural killer T (iNKT) cells, which comprise about 30% of hepatic lymphocytes, are stimulated by amebic lipopeptidephosphoglycan (LPPG) to release IFN-γ. Production of IFN-γ reduces parasite burden and controls abscess formation.[28]

Adaptive Immunity

Secretory IgA responses against *E. histolytica* have been well characterized and shown to correlate with protection against infection and disease. For this reason, vaccines designed to generate IgA antibodies against the Gal/Gal/NAc lectin have been highly efficacious in preventing experimental *E. histolytica* infection in mice and baboons.[28] However, the role of antilectin IgG is unclear, and protection may be subclass-dependent. Cell-mediated immunity is also critical for host defense against *E. histolytica.* IFN-γ–producing CD4 T cells provide protection through their ability to activate macrophages and neutrophils to the parasite. CD8 T cells mediate protection through the secretion of IL-17, a key player in the secretion of mucin and antimicrobial peptides, recruitment of neutrophils, and IgA transport across the epithelial barrier. Impairment of cell-mediated immunity results in parasite dissemination. Indeed, patients with human immunodeficiency virus infection and coinfected with *E. histolytica* have high rates of invasive amebiasis, liver abscesses, and seroconversion.[29]

Evasion of Host Immunity

E. histolytica utilizes a number of strategies to circumvent the immune defenses of the host. It resists complement-mediated lysis during hematogenous spread by proteolytic degradation of C3a and C3b. In addition, the Gal/GalNAc lectin binds to C8 and C9, preventing assembly of the C5b-9 membrane attack complex. The cytolytic capability of *E. histolytica* affords protection from neutrophils, macrophages, and eosinophils, unless these cells are activated. Cytolysis by *E. histolytica* can occur via necrosis and apoptosis. Trophozoites also inhibit the macrophage respiratory burst and the production of IL-1 and TNF-α. A protective antibody response is subverted by the degradation of IgA and IgG by amebic cysteine proteases and by capping, ingesting, or

FIG 30.3 **Immunopathogenesis of Intestinal Protozoal Pathogens.** After adherence (*Giardia* and *Entamoeba*) or epithelial invasion (*Entamoeba* and *Cryptosporidium*), there is release of various inflammatory mediators from macrophages and neutrophils. This causes the activation of resident phagocytes and recruitment of phagocytes into the lamina propria. Enterocyte death can be due to direct action of the parasites or to immune-mediated damage from complement, cytotoxic lymphocytes, proteases, and reactive oxygen and nitrogen intermediates (ROI and RNI, respectively). The inflammatory mediators also act on enterocytes and the enteric nervous system, inducing the secretion of water and chloride. In response to enterocyte damage, under the influence of activated T lymphocytes, the crypts undergo hyperplasia, and the villi become shorter (villous atrophy). The immature hyperplastic cells have poor absorptive ability but retain secretory ability. Damage to the epithelium can cause leakage (exudation) from lymphatics and capillaries. Similar mechanisms are probably responsible for the diarrhea that occurs in infection with *Cyclospora* and *Isospora*. *Isospora* is unique in causing an eosinophilic infiltrate.

shedding ameba-specific antibodies.[27] Amebic proteases can also cleave the Fc region so that interaction with host cell surface receptors is avoided. Another secreted product of *E. histolytica*, monocyte locomotion inhibition factor (MLIF), inhibits monocyte locomotion and the monocyte and neutrophil respiratory burst and NO production; enhances antiinflammatory cytokine and chemokine release from host cells; and alters adhesion molecule expression on macrophages. The suppression of host macrophage NO production by an array of trophozoite secretory products, including parasite-derived PGE_2, is a major factor in the persistence of amebic liver abscesses. In chronic infection, *E. histolytica* promotes the development of Tregs that suppress the proliferation of responder T cells by releasing IL-10, TGF-β, and IL-35.[28]

Giardia lamblia

Pathogenesis

Recent studies of *Giardia lamblia* have identified eight genotypes, two of which infect humans (assemblages A and B).[30] The severity of giardiasis ranges from asymptomatic carriage to chronic watery diarrhea, epigastric pain, nausea, vomiting, and weight loss, depending on host factors and the virulence of the *Giardia* strain.[30,31] Recent studies suggest even with treatment the parasite can elicit intestinal complications that persist for years. Younger age, malnutrition, and immunodeficiency increase the risk of severe disease.[31] Infection is initiated following the ingestion of food or water contaminated with *G. lamblia* cysts. Exposure to stomach acids induces the excystation process that releases two trophozoites into the lumen of the proximal small intestine. Colonization occurs when the parasite attaches to the intestinal epithelium and begins to reproduce by binary fission. Trophozoites remain within the lumen and do not invade the epithelial barrier. Parasite migration into the lower intestine triggers encystation, allowing the organism to survive when excreted into the environment.

The *G. lamblia* trophozoite initiates adherence to the intestinal epithelium via a surface mannose-binding lectin. Histopathological changes in symptomatic giardiasis range from a normal appearance to increased crypt-villous ratios, epithelial damage, and chronic inflammatory infiltrate in the lamina propria (see

Fig. 30.3). The factors responsible for the structural changes in the small bowel are not well defined but may include injury from adherence, parasite-induced apoptosis of epithelial cells, and the release of cytotoxins, including proteases. Additional epithelial damage may be mediated by the host cellular immune response. Diarrhea arises from epithelial barrier dysfunction, reduction in microvillous surface area, chloride hypersecretion, and glucose and sodium malabsorption.[31]

Innate Immunity

As *G. lamblia* does not invade the intestinal epithelium, host defense and immune factors present within the lumen are essential for preventing and controlling infection. Increased intestinal motility contributes to *G. lamblia* clearance, by impairing the ability of the parasite to attach to the epithelium and resist the luminal bulk flow. Antimicrobial peptides derived from Paneth cells, including cryptdins, neutrophil defensin, and cathelicidin, effectively kill *G. lamblia* trophozoites *in vitro*.

NO, produced by both epithelial cells and macrophages, inhibits excystation trophozoite division. Despite the protective effect of NO, the parasite can circumvent this defense by competing with host cells for arginine uptake.[30] Mast cells have a significant role in protecting against the parasite. Mice deficient in mast cells fail to clear *G. lamblia* infection, in part because they are unable to mount parasite-specific IgA. Mast cells also contribute to B-cell survival, activation and differentiation into plasma cells, and together with NO induce peristalsis.

Adaptive Immunity

Several lines of evidence suggest the importance of the humoral immune response in the control of giardiasis. Infection with *Giardia* results in the production of anti-*Giardia* antibodies in the serum and mucosal secretions. Patients with severe B-cell defects or selective IgA deficiency have an increased risk of developing chronic infections.[30] Studies in mice have demonstrated key functions of secretory IgA and the polymeric immunoglobulin receptor, which is responsible for IgA transport into the intestinal lumen in controlling parasite burden and eliminating infection.[30]

There is also evidence for a role of T cell–dependent immunity in the control of giardiasis. A reduction or absence of CD4 T cells can lead to chronic infection. IFN-γ- and IL-17A-producing CD4 T cells develop following infection[32] and are important for mediating parasite clearance. Although the mechanisms are still being defined, IL-17A is likely involved in modulating transport of IgA into the intestinal lumen. Epidemiological studies indicate that partial immunity is acquired from *Giardia* infection, which leads to reduced risk and severity of subsequent infections.[30]

Evasion of Host Immunity

Giardia evades the host humoral immune response by undergoing surface antigenic variation by altering a group of variant-specific surface proteins (VSPs). Selection occurs by an immune-mediated process because switching occurs when intestinal anti-VSP IgA responses are first detected.[30] *G. lamblia* also produces a protease that cleaves IgA. Although *Giardia* activates dendritic cells for antigen presentation, it also inhibits IL-12 production, in part by enhancing IL-10 release; the net result is the dampening of a local antiparasitical inflammatory response.[30] The trophozoite also releases arginine deiminase, which degrades arginine, making it less available for host NO production.[31]

Cryptosporidium parvum AND *Cryptosporidium hominis*

In humans, there are four intestinal coccidians that are intracellular parasites of enterocytes: *Isospora belli*, *Cyclospora cayetanensis*, and two species of *Cryptosporidium*, *C. parvum*, and *C. hominis*. Of the four coccidians, *Cryptosporidium* has the greatest epidemiological significance: in 1993, a huge outbreak involving 403 000 persons occurred in Milwaukee, Wisconsin, in the United States. Because of their similarity, only the immunology of cryptosporidiosis will be discussed.

Pathogenesis

Cryptosporidium typically causes self-limited (but often prolonged) diarrhea in the immunocompetent host. However, in the immunocompromised host *Cryptosporidium* can cause severe diarrhea, with malabsorption and wasting, and cholangiopathy. Infection begins with the ingestion of food or water contaminated with oocysts. The acidic environment of the stomach induces excystation and the release of four sporozoites into the small intestines. Glycoproteins on the surface of sporozoites facilitate attachment and invasion of epithelial cells. After entry into epithelial cells, the parasite resides within a unique intracellular but extracytoplasmic vacuole, that protects the pathogen from environmental and host insults. Inside a vacuole the sporozoites develop into trophozoites and undergo schizogony, with a resultant merozoite-containing schizont. The merozoites are extruded and invade neighboring epithelial cells. The merozoites may continue an asexual cycle or develop into macro- or microgametes that fuse to form oocysts. Before being excreted in feces, oocysts undergo sporulation to become infectious. Histologically, infection causes villous atrophy and blunting, and crypt hyperplasia with increased infiltration of lymphocytes, macrophages, and plasma cells.[33] Intraepithelial lymphocytes are uncommon; neutrophils and occasional eosinophils are present between the epithelium and the lamina propria. Disorganized cells undergoing necrosis replace normal enterocyte architecture (see Fig. 30.3). There is an association between the degree of intestinal injury and malabsorption and the intensity of infection, as measured by oocyst excretion.

The neuropeptide substance P, which is produced by endothelial cells, lymphocytes, and monocytes in the lamina propria, contributes to diarrhea by increasing intestinal chloride secretion and glucose malabsorption. Increased expression of substance P is observed in patients with AIDS as well as cryptosporidiosis and severe diarrhea.[34]

Innate Immunity

The type I and type II IFNs play a key role in the innate protective response against cryptosporidium.[35] Because of the parasite's intracellular location near the luminal surface of the enterocyte, the macrophages of the lamina propria are spatially isolated from the parasite. Thus the intestinal epithelium mounts its own assault on the invading microbe through TLR2/TLR4–dependent activation of NF-κB and release of the microbicidal peptide β-defensin-2, TNF-α, and the chemokines IL-8, RANTES, and GRO-α, which act as chemoattractants and activators of neutrophils. In patients with AIDS and cryptosporidiosis, the HIV Tat protein may sabotage host defense against *Cryptosporidium* by inhibiting cholangiocyte TLR4 expression.[33]

IL-15, produced by activated monocytes, stimulates NK-cell proliferation, cytotoxicity, and cytokine production, including IFN-γ. There is significant IL-15 expression in the jejunal mucosa in immunocompetent patients with cryptosporidiosis, and IL-15 levels inversely correlate with parasite burden. However, in patients with AIDS who have chronic uncontrolled cryptosporidiosis, IL-15 is undetectable.[33]

Mannose-binding lectin (MBL) is a serum protein that binds to various pathogens, including *Cryptosporidium.* Upon binding, MBL activates complement, thereby promoting opsonization and phagocytosis. Low serum levels of MBL, which may result from malnutrition or polymorphisms in the *MBL2* gene, increase susceptibility to cryptosporidiosis.[33] Infected intestinal cells also release TGF-β, which decreases necrosis and stimulates the synthesis of extracellular matrix proteins, thereby limiting epithelial damage.

Prostaglandins E_2 and $F_2\alpha$, released by infected enterocytes, not only promote secretory diarrhea but also upregulate mucin production, which may hinder parasite attachment. In addition, these prostaglandins stimulate the release of β-defensin-2, which has direct anticryptosporidial activity and is chemotactic for T cells and DCs.[33]

Adaptive Immunity

Cell-mediated immunity plays an important role the resolution of cryptosporidiosis and protection from reinfection. In immunocompetent, adult mice CD4 intraepithelial lymphocytes (IELs) initiate early control of infection, whereas cytotoxic CD8 IELs appear later and function in parasite elimination. Resolution of infection depends on a balance of Th1 cytokines (IFN-γ, IL-18) needed to control the infection and Th2 cytokines (IL-4, IL-10, and IL-13) that limit immunopathological damage. In mice, γδ T cells are rapidly recruited to control cryptosporidial infection, but their role in human infection is unknown. Severe intestinal disease or biliary involvement is usually seen in patients with AIDS whose CD4 count is <50/μL.[33] Patients with HIV infection who have CD4 counts >200/μL usually experience self-limited disease.

The role of humoral immunity is less clear. Secretory antibodies produced in the intestines are thought to impair parasite attachment to epithelial cells. Indeed, immunoglobulin deficiencies are often associated with persistent or recurrent infections. However, specific anti-*Cryptosporidium* IgA levels have been reported in patients with AIDS who are infected with the parasite, suggesting polyreactive T cell–independent antibodies are not sufficient for parasite eradication.[33] In experimentally infected human volunteers, serum IgM and IgG directed toward sporozoite proteins protect against the development of symptoms, but not infection.

Evasion of Host Immunity

Cryptosporidium evades host defenses primarily by exerting control over infected enterocyte apoptosis. One of the upregulated genes is osteoprotegerin, which inhibits apoptosis by acting as a decoy receptor for TNF-related apoptosis inducing ligand (TRAIL).[34] Control of host apoptosis is complex; early inhibition of apoptosis by NF-κB activation allows the parasite to complete its life cycle, whereas the late promotion of apoptosis facilitates merozoite release. Nevertheless, the infected cells secrete FasL, which promotes apoptosis in uninfected bystander cells. In this way, the host counters the antiapoptotic activity of the parasite by surrounding the parasitized cells by a zone of apoptotic cells.

Trichomonas vaginalis

Pathogenesis

Trichomonas vaginalis is a flagellated protozoan parasite of the human urogenital tract that exists only as a trophozoite. It causes vaginitis, cervicitis, and urethritis. Its adherence to the vaginal squamous epithelium is facilitated by a number of adhesins. *Trichomonas* causes tissue damage by contact-dependent cytolysis caused by pore-forming proteins and proteases, and secretion of a glycoprotein cell-detaching factor that causes sloughing of the vaginal epithelium. Levels of the cell-detaching factor correlate with the severity of the disease, and vaginal antibodies directed against this factor modulate its effects. Inflammation in the genital mucosa and submucosa leads to copious secretions, and the surface epithelium may slough, causing focal erosions and hemorrhage.

The increased risk of HIV transmission in women with trichomoniasis may result from increased recruitment of inflammatory cells, mucosal erosion, or degradation of secretory leukocyte protease inhibitor (SLPI) by trichomonal proteases. Lower levels of SLPI are found in the vaginal fluid of women with trichomoniasis, which can lead to increased tissue damage and HIV transmission.[36] The lipophosphoglycan of *Trichomonas* induces production of the chemokines IL-8 and CCL20, which, which can also facilitate HIV infection by promoting DC recruitment.

Innate Immunity

Although trichomoniasis has recently received increased attention as a risk factor for HIV transmission and obstetrical complications, there is little known about the protective immune response against this organism. *Trichomonas* secretes a factor that promotes neutrophil chemotaxis, causing profuse leukorrhea, but the oxidative microbicidal mechanisms of the neutrophils have decreased efficacy in the anaerobic vaginal environment. Activated macrophages can destroy trichomonads in a T and B cell–independent manner and release IL-lβ and TNF-α, which are chemotactic for neutrophils.[37] *Trichomonas* induces neutrophil apoptosis, and macrophage clearance of these apoptotic cells causes release of IL-10, which may contribute to resolution of the inflammatory response.[38]

Adaptive Immunity

Repeated infections with *T. vaginalis* do not induce immunity; however, the infection is self-limited in most cases, so there are effective mechanisms of host defense. *T. vaginalis* induces the production of antibodies in both the serum and vaginal secretions. The serum antibody response correlates with active infection, and serum, but not vaginal, IgG from infected patients displays complement-mediated lytic activity against trichomonads in culture.[38]

Evasion of Host Immunity

Although *T. vaginalis* activates the alternative pathway of complement, the cervical mucus and menstrual blood are low in complement. Menstrual blood also supplies iron, which upregulates trichomonal adhesins and cysteine proteases, causing the degradation of complement component C3 bound to the surface of the parasite. Parasite virulence is thus enhanced, and the symptoms are exacerbated during menses. Cysteine proteases secreted by *T. vaginalis* also degrade immunoglobulins, sabotaging the antibody response. The parasite also secretes soluble antigens that act as decoys for neutralizing antibodies or cytotoxic T cells and disguises itself by binding to host plasma proteins. Phenotypic variation of surface markers is also a means of antibody evasion.[38]

ON THE HORIZON

Anticipated Approaches to Improved Control of Protozoal Diseases

- Gaining insight into the role of host genetics, gender, intestinal microbiota, and nutritional status in the outcome of protozoal infections
- Defining host immune and inflammatory mechanisms that promote disease caused by protozoal pathogens
- Understanding mechanisms for sustained generation of protective immunity against protozoal pathogens
- Developing vaccines for several blood and tissue protozoa
- Developing new host-directed treatment strategies to overcome immune evasion by protozoal pathogens

MULTIPLE-CHOICE QUESTIONS

1. Which one of the following is characteristic of the immunopathogenesis of cerebral malaria?
   - **A.** Absence of *Plasmodium*-specific antibodies
   - **B.** Impaired interferon (IFN)-γ mediated production of nitric oxide
   - **C.** Cytoadhesion of parasites and leukocytes to vascular endothelium
   - **D.** Immune-mediated destruction of infected erythrocytes
   - **E.** Failure of leukocyte production of leukotriene/tumor necrosis factor (LT/TNF)
2. Which one of the following is NOT a mechanism through which *Leishmania* can evade the host immune response?
   - **A.** Complement resistance mediated by the parasite's surface lipophosphoglycan
   - **B.** Blunted interferon (IFN)-γ-mediated macrophage activation through the disruption of signal transduction pathways
   - **C.** Increased synthesis of the immunosuppressive molecules interleukin (IL)-10, transforming growth factor (TGF)-β, and prostaglandin (PG)E_2
   - **D.** Depletion of L-arginine through the activity of host arginase
   - **E.** Suppression of an early neutrophil response at the site of infection
3. Which one of the following is a component of the innate immune response to *Cryptosporidium infection?*
   - **A.** Decreased intestinal mucin production
   - **B.** Increased type I and type II interferon production
   - **C.** Decreased nuclear factor-kappa B (NF-κB) activation
   - **D.** Antigen-specific CD8 intraepithelial T-cell responses
   - **E.** Antigen-specific immunoglobulin A (IgA) responses

Immune Responses to Helminth Infection

Subash Babu, Thomas B. Nutman

Parasitical helminths are complex eukaryotic organisms, characterized by their ability to maintain long-standing, chronic infections in human hosts, sometimes lasting decades. Hence, parasitical helminths are a major health care problem worldwide, infecting more than 2 billion people, mostly in resource-constrained countries (Fig. 31.1). Common helminth infections include those with intestinal helminths, and filarial and schistosome infections are a major medical, social, and economic burden to the countries in which these infections are endemic. Chemotherapy, although highly successful in some areas, still suffers from the disadvantages of the length of treatment, the logistics involved in the distribution of drugs, and, in some cases, the emergence of drug resistance. Vector control measures are at best an adjunct measure in the control of helminth infections but also suffer from the same social, logistic, and economic obstacles as those for mass chemotherapy. Therefore the study of the immune responses to helminth infections attains great importance both in terms of understanding the parasite strategies involved in establishing chronic infection and in the delineation of a successful host immune response to develop protective vaccines against infection.

SPECTRUM OF HOST–PARASITE INTERACTIONS

Helminths have characteristically complex lifecycles with many developmental stages.[1] Thus the host is exposed during the course of a single infection to multiple lifecycle stages of the parasites, each stage with a shared as well as a unique antigenic repertoire. Thus *Schistosoma mansoni* infection begins with penetration of the skin of humans exposed to infested waters by the free-swimming cercariae, which then develop into tissue-dwelling schistosomula. In the liver and mesenteric veins, schistosomula differentiate into sexually dimorphic adult worms, which then mate, and the resultant eggs produced migrate through tissues into the lumen of the intestine or bladder for environmental release. Similarly, in lymphatic filarial infection, the host is exposed to infective-stage larvae in skin, lymph nodes, and lymphatics; to adult worms in lymph nodes and lymphatics; and finally to microfilariae in the peripheral circulation. Hence, the host–helminth interaction is complex not only because of the multiple lifecycle stages of the parasite but also because of the tissue tropism of the different stages.

Antigenic differences among the lifecycle stages can lead to distinct immune responses that evolve differentially over the course of a helminth infection. In addition, depending on the location of the parasite, the responses are compartmentalized (intestinal mucosa and draining lymph nodes in intestinal nematode infection, or skin/subcutaneous tissue and draining lymph nodes in onchocerciasis) or systemic (lymphatic filariasis or schistosomiasis). Moreover, the migration patterns of the parasite might elicit varied cutaneous, pulmonary, and intestinal inflammatory pathologies, as seen, for example, in *Ascaris* or *Strongyloides* infection during their migratory phase. This is further complicated by the fact that human hosts are often exposed to multiple lifecycle stages of the parasite at the same time. Thus a patient with chronic infection with lymphatic filariasis harboring adult worms and microfilariae might be exposed to insect bites, thereby transmitting the infective-stage parasite. The immune response that ensues will not only be a reaction to the invading organism but will also bear an imprint of the previous exposures and the concurrent infection.

KEY CONCEPTS

Helminth Infection

- Divided into nematodes, trematodes, and cestodes
- Produce chronic infections that can persist for decades
- Characteristically cause morbidity rather than mortality
- Multicellular parasites that do not multiply in the definitive host but can reproduce sexually to produce larval stages that ensure continued transmission

Helminth infections can elicit a spectrum of clinical manifestations mirroring diversity in host immune responses. For example, in lymphatic filariasis, most infected individuals remain clinically asymptomatic despite harboring significant worm burdens; this is thought to reflect the induction of parasite-specific tolerance in the immune system. Others exhibit acute manifestations, including fever and lymphadenopathy, and this is thought to reflect inflammatory processes induced by incoming larvae, dying worms, or superadded infections. Individuals who mount a strong but inappropriate immune response end up with lymphatic damage and subsequent immune-mediated pathology—hydrocele and elephantiasis. Finally, a group of infected individuals mount exuberant immune responses that often result in unusual pathology, such as tropical pulmonary eosinophilia. Thus the clinical manifestations of lymphatic filariasis exemplify the spectrum of host–parasite interactions that occur during helminth infections (Fig. 31.2).

Another hallmark of all helminth infections is their chronic nature, with many helminths surviving in the host for decades. For example, adult schistosomes and filariae may survive in host tissues for as long as 30 years, producing eggs and larval stages throughout this time. Similarly, *Strongyloides stercoralis*, with its ability to “autoinfect,” can maintain its lifecycle for decades. Chronic infections certainly reflect an adaptation that leads to “parasitism,” as mortality induced in the host would prevent parasite transmission if the host died before larval release or egg production could occur. In addition to the long-lived nature of the infection, helminths appear to reflect a harmonious host–parasite interface such that relatively asymptomatic carriers are available as reservoirs for ongoing transmission. Of course, failure to establish this harmonious coexistence does occur, leading to pathological conditions exemplified by cirrhosis and portal hypertension in schistosomiasis and elephantiasis associated with lymphatic filariasis.

PROTOTYPICAL HOST RESPONSES TO HELMINTHS

The canonical host immune response to all helminths is of the T-helper 2 (Th2) type and involves the production of cytokines interleukin (IL)-4, IL-5, IL-9, IL-10, and IL-13; the antibody isotypes immunoglobulin G1 (IgG1), IgG4, and IgE; and expanded populations of eosinophils, basophils, mast cells, type 2 innate lymphoid cells, and alternatively activated macrophages[2] (Chapter 16). However, it is also being increasingly recognized that while the predominant response is Th2 in nature, a large regulatory component involving both regulatory cytokines and cells are also part of this repertoire.[3] The Th2 response induced by helminth parasites is quite stereotypical, but its initiation, progression, and culmination of this response requires interaction with many different cell types, most notably *(i)* epithelial/stromal cells, *(ii)* innate lymphoid cells (ILCs), *(iii)* dendritic cells (DCs) and macrophages; *(iv)* T cells; *(v)* B cells; *(vi)* eosinophils; *(vii)* mast cells/basophils; and *(viii)* neutrophils (Chapter 2). In addition, the host–helminth interactions can lead to a variety of modulated immune responses that are mediated largely by the induction of regulatory T cells (Tregs) and alternatively activated macrophages (AAMs) (Fig. 31.3).

Helminths and Epithelial Cells

Epithelial cells are the first barrier layer exposed to or breached by most helminths, and the capacity of these cells to respond by initiating an "alarm" response has recently been recognized.[4] These epithelial cells mount a prototypical response comprising chemokines and cytokines, such as IL-1, IL-25, IL-33, and thymic stromal lymphopoietin (TSLP), as well as alarmins, such as uric acid, ATB, HMGB1, and S100 proteins. These signals program DCs to mount Th2 cell–mediated immunity and in doing so boost type 2 innate lymphoid cell (ILC2), basophil, and mast cell function. Epithelial cells produce chemokines, including CCL17 and CCL22 (acting on ILC2, basophils, Th2 cells, and Tregs), and eotaxins, such as CCL11, CCL24, and CCL26 (acting on eosinophils and Th2 cells). They also produce prostaglandin D2 (PGD2), which acts on the CRTH2 receptor to recruit ILC2, basophils, mast cells, and Th2 cells. More recently, tuft cells, a specialized secretory cell type of the intestinal epithelium, has been identified as a major player in anthelmintic immunity. In addition, epithelial cells in the intestine, for instance, are in constant contact with both beneficial and pathogenic bacteria and hence ideally located for immunological surveillance of the intestinal lumen. This recognition of signals by intestinal epithelial cells is essential to mucosal homeostasis, implicating these cells as central modulators of inflammatory responses. Finally, the production of mucus and mucus-associated bioactive molecules (Mucin5AC, trefoil factor-2, and resistin-like molecule-β [RELM-β]) are important in promoting protection against intestinal helminth infection.

Helminths and Innate Lymphoid Cells

The ILC family includes ILC1, which predominantly express IFN-γ; ILC2, which predominantly express IL-5 and IL-13; and ILC3; which predominantly express IL-22 and/or IL-17.[5] ILC2 are defined by their expression of the IL-33 receptor (IL-33R) and the transcriptional regulators, Id2, RORα, GATA-3, and Bcl11b. Unlike T cells, ILC2 rely on cytokines to drive activation rather than on cognate interactions mediated by antigen-specific receptors. ILC2 are a critical innate source of type 2 cytokines, including moderately large quantities of IL-5 and IL-13, but also of IL-4, IL-9, granulocyte macrophage–colony-stimulating factor (GM-CSF), and amphiregulin. These cytokines potently induce eosinophilia, mucus production from goblet cells, activation of AAM, muscle contractility, mastocytosis, and tissue repair.[5] They are dependent on IL-2 and IL-7 for their development and activation. In addition, the transcription factors GATA-3 and RORα have been found to be essential for the development of ILC2. Although the function of ILC2 and Th2 cells appear to be largely overlapping, the kinetic differences in the ability to secrete cytokines rapidly and in profuse amounts allows for a coordinated interaction between the two cell types. Moreover, ILC2 can directly regulate the activation of T cells through their expression of major histocompatibility complex (MHC) Class II molecules and the accessory molecules, CD80 and CD86, albeit less efficiently compared with DCs. Finally, recent reports have linked ILC2 with metabolic homeostasis, obesity, and dietary stress, providing an indirect link by which helminths might modulate host metabolic function.

Helminths and Dendritic Cells

DCs are professional antigen-presenting cells (APCs) that play an essential role in presenting antigen to T cells to initiate immune responses.[2] Although the role of DCs in inducing Th1, Th17, and Treg responses is well established, their role in inducing Th2 responses has remained relatively unclear. Nevertheless, a series of studies have shown that DCs are required for optimal Th2 responses *in vivo*. Thus *in vivo* depletion of DCs has been shown to inhibit the induction of Th2 responses to *S. mansoni* or *Heligmosomoides polygyrus.* Helminth products can prime DCs for the induction of Th2 responses by interaction with pattern recognition receptors (PRRs), such as Toll-like receptors (TLRs) and C-type lectin receptors (CLRs). This interaction, which depends on TLR and CLR signaling, can promote Th2 responses by suppressing antigen presentation, costimulation, and/or expression of Th1-promoting cytokines by directly interfering with these pathways. DCs that drive Th2 responses typically exhibit specialized markers, such as CD301b, PDL2, and CD11b, and several receptors for the Th2-related cytokines IL-4R, IL-13R, IL-25R, TSLP-R, and IL-33R. Additionally, the extracellular signal-regulated kinase (ERK) and signal transducer and activator of transcription 4 (STAT4) pathway upregulates the costimulatory molecules, CD40, OX40L, and Jagged. Activation of the major transcription factors interferon regulatory factor 4 (IRF4) and KLF4 inhibits IL-12 production and increased IL-10 secretion. In addition, DCs expressing FcεRIII can induce murine IgG1-related Th2 responses. These factors typically act individually or in concert to orchestrate Th2 responses in helminth infections. Although Th2 cell–mediated immunity requires IRF4-dependent CD301b$^+$CD11b$^+$ DCs in the mouse, Langerhans cells are the predominant inducers of Th2 cells *ex vivo* in humans. The modulation of DC function by helminth antigens appears to be generalizable and has been shown to impair their ability to respond to other infectious stimuli (*e.g., Mycobacterium tuberculosis*).

Helminths and Macrophages

Macrophages are the other important class of APCs that can serve as protective effector cells in bacterial and protozoan infections by their production of nitric oxide and other mediators. Helminth interaction with macrophages induces a population of cells preferentially expressing arginase instead of nitric oxide as a result of increased activation of *arginase-1* by IL-4 and IL-13.[6] These AAMs are characterized by their ability to upregulate arginase-1, chitinase 3-like proteins 3 and 4 (also known as Ym1 and Ym2, respectively), and RELM-α. These AAMs are known to be important in wound healing and have been postulated to play a potential role in repairing wound damage that occurs during tissue migration of helminth parasites. In fact, there appears to be two distinct populations of AAMs, one derived from blood and functioning in an immune regulatory role and the other derived from tissue-resident macrophages apparently responsible for much of the fibrosis seen in chronic helminth infections. By virtue of the expression of regulatory molecules, such as IL-10, TGF-β, and programmed cell death 1 ligand 2 (PDL2), these AAMs may have a predominantly regulatory role in helminth infections. These antiinflammatory macrophages function through arginase-1, PDL2, triggering receptor expressed on myeloid cells 2 (TREM2) and RELM-α to inhibit classic macrophage inflammation and recruitment and T-cell responses. Similarly, macrophage-derived human resistin is induced by helminth infection and promotes inflammatory responses and increased susceptibility.

Helminths and T Cells

Typically, infections with helminths induce a robust Th2 response manifested by enhanced expression of IL-4, IL-5, IL-9, IL-10, and IL-13 in response to live parasites, parasite antigens, or mitogens.[7] The central player in Th2 immunity is certainly the CD4$^+$ Th2 cell. It is clear that IL-4Rα, a component of both the IL-4 and IL-13 receptors, is at the epicenter of Th2 immunity, since IL-4 and IL-13, together or individually, are absolutely critical for resistance to most helminth parasites. Recent work has reported that the Th2 cell population is heterogeneous, containing both IL-5$^+$ and IL-5$^-$ Th2 cells that express IL-4 and IL-13. In addition, IL-4 and IL-13 production is spatially separated, with IL-13 expression being marked in tissues and IL-4 expression being pronounced in the lymph nodes within the Th2 cell compartment. Finally, induction of GATA-3 and downregulation of T-box expressed in T cells (T-bet) has been shown to be an important step in T resistin-like molecule cell differentiation to the Th2 phenotype in helminth infections. Interestingly, chronic helminth infections are associated with downmodulation of parasite antigen-specific proliferative responses as well as IFN-γ and IL-2 production but with intact IL-4 responses to parasite antigens and global downregulation of both Th1 and Th2 responses to live parasites. Finally, the receptor NLRP3 has been shown to be a key transcription factor in Th2 differentiation.

Although the role of tissue resident memory T (T_{RM}) cells is well established in viral and bacterial infections, very little is known about the role of these cells in helminth infections. However, it has been shown that tissue-resident Th2 cells can exert innate (TCR-independent and IL-33–dependent) functions upon appropriate stimuli and confer protection against helminth infection. In addition, although multifunctionality (ability to produce two or more cytokines) has not been well described in the Th2 cell compartment, helminth infections are known to be associated with an antigen-dependent enhancement of mono- and dual-functional Th2 cells and its reversal after treatment. Of interest, a stable subset of parasite induced T-bet$^+$, GATA-3$^+$, Th1/Th2 hybrid T cells has been described to develop directly from naïve precursors and to play a role in limiting pathological inflammation in animal models of helminth infection.

Recently, a new subset of T cells expressing IL-9 and IL-10, but not IL-4 (and therefore different from Th2 cells), has been described in allergic inflammation and in response to intestinal parasites.[8] These cells appear to be under the control of TGF-β and IL-4 and are dependent on STAT6, GATA-3, IRF4, and PU.1. Th9 cells have been recently shown to be associated with host protection in *Nippostrongylus brasiliensis* and *Trichuris muris* infection. Finally, Th9 cells have also been shown to be predominantly associated with lymphatic pathology in filariasis. T-follicular helper (Tfh) cells are a subset of CD4 T cells that migrate to B-cell follicles after activation and promote germinal center formation and B-cell isotype switching.[9] These cells, which form an independent lineage of CD4 T cells, have been recently identified to be the predominant IL-4 producing T cells early in helminth infection. In addition, Tfh are major producers of IL-21, a cytokine that plays a crucial role in supporting polarized Th2 responses *in vivo.*

Th17 cells, another subset of CD4 T cells, express the prototypical cytokine—IL-17. In terms of helminth infections, the role of Th17 cells has been primarily studied in animal models of *S.*

mansoni, where it has been strongly associated with infection-induced, immune-mediated pathology.[10] More recently, it has also been demonstrated in human infections, in which children with *S. hematobium*–associated pathology have higher Th17 responses compared with those who are pathology-free. Similarly, a strong association of Th17 responses with pathological responses has also been demonstrated in lymphatic filariasis. Finally, Th22 cells are yet another subset of CD4 T cells that typically secrete IL-22. To date, only a few studies have examined the role of Th22 cells in helminth infections.[11] IL-22 was shown to be induced in the intestinal mucosa after infection with *T. trichiura* or *Necator americanus* in humans, whereas the frequency of Th22 cells was shown to be higher in individuals with filarial infection compared with endemic healthy controls.

Helminths and B Cells

Helminth interactions with B cells occur both at the B-cell cytokine level and at the level of antibody production. Interactions at the cellular level primarily result in B-cell activation and cytokine production, most notably by the induction of IL-10. B cells have been shown to be important for the Th2 responses to certain helminths, with IL-2 producing B cells supporting optimal development of effector and memory Th2 cells and LTα1β2-expressing B cells supporting the recruitment of a Th2 promoting DCs.[12] Immune regulation by B cells has also been recognized in schistosome infection, where B-cell deficiency leads to enhanced Th2 cell–dependent immunopathology. However, it is at the level of antibody production that B cells play a profound role in helminth infections. Susceptibility to secondary infection is increased in the absence of B cells in infection with *Litomosoides sigmodontis, S. mansoni, T. muris,* and *Heligmosomoides polygyrus bakeri.*[13] IgG is reported as an antibody isotype that is important for protection against intestinal helminths, and IgM (typically produced in a T cell–independent manner) has been linked to timely elimination of filarial parasites. One of the most consistent findings in helminth infections, both in mice and humans, is the elevated level of IgE that is observed after exposure to helminths. Most of the IgE produced is not antigen specific, perhaps representing nonspecific potentiation of IgE-producing B cells or deregulation of a normally well-controlled immune response. Interestingly, these IgE antibodies persist many years after the infection has been treated, indicating the presence of long-lived memory B cells or plasma cells in helminth infections. IgE production both in mice and humans is absolutely dependent on IL-4 or IL-13. Other isotypes that are commonly elevated in humans with chronic helminth infection are IgG4 and IgG1, the former being most dependent on both IL-4 and IL-10. Recent studies have highlighted the role of regulatory B cells in suppression of immune responses to helminth parasites. This B-cell function involves the secretion of IL-10 and IL-35 and is similar to the regulatory activity of B cells in autoimmune diseases.

Helminths and Eosinophils

Blood and tissue eosinophilia is characteristic of helminth infection and is mediated by IL-5 (probably in concert with IL-3 and GM-CSF). Recruitment of eosinophils to the site of infection occurs very early in experimental helminth infection—as early as 24 hours after exposure. Kinetics of blood eosinophilia in humans is harder to determine but is postulated to occur as early as 2–3 weeks after infection, as demonstrated in experimental infections of volunteers.[14] Both basal eosinophil levels and tissue accumulation during helminth infection appear to be under the influence of ILC2. Apart from the rapid kinetics of recruitment, eosinophils in blood and tissue also exhibit morphological and functional changes attributable to eosinophil activation. Eosinophils possess a range of immunomodulatory factors that are released upon cell activation, including cytokines, growth factors, and chemokines. Unlike T and B cells, eosinophils can rapidly release cytokines within minutes in response to stimulation, since most of the cytokines are stored in a preformed fashion in secretory vesicles. Moreover, eosinophils can participate in the regulation of IgE and goblet cell mucus production; they also serve as effector cells in protective immune responses and as regulatory cells influencing both innate and adaptive immunity in helminth infections.

Helminths and Basophils/Mast Cells

Basophils are an important component of the immune response to helminth infections.[15] Basophils are capable of secreting a variety of mediators, including histamines, cytokines, chemokines, and lipid mediators that promote Th2 responses. Basophils in humans and mice also readily generate large quantities of IL-4 in IgE-dependent and IgE-independent manners. Basophils appear to play an important role in protective immunity to secondary infection (similar to eosinophils) with *N. brasiliensis, H. polygyrus bakeri,* and *L. sigmodontis;* they also play an active role in resistance to primary infection (through secretion of IL-4 and IL-13) with *T. muris* and *T. spiralis.* In addition, basophils have been shown to be critical APCs for driving Th2 cell differentiation in different models of helminth infection.

Mast cells may contribute to inflammatory reactions directed against invasive helminth parasites. These cells express high affinity Fcε receptors that are sensitized with parasite antigen–specific IgE and can be triggered by parasite antigens. It has been postulated that cytokines and other mediators released by sensitized mast cells contribute to *(i)* the recruitment and activation of effector eosinophils; *(ii)* increased local concentrations of antibody and complement; and *(iii)* enhanced mucus hypersecretion and increased peristalsis of the gastrointestinal (GI) tract that plays an important role in resistance to certain GI nematode infections.[16] More recently, a role for mast cells (in an IgE-independent manner) in mediating the secretion of epithelial-derived cytokines (IL-25, IL-33, and TSLP) and optimal migration of DCs was shown in *H. polygyrus bakeri* infection.

Helminths and Neutrophils

Although neutrophils are typically considered more important in bacterial and fungal infections, a number of studies have revealed that neutrophils can act in conjunction with macrophages to contain or kill helminth parasites.[17] Thus neutrophils are major components of the granulomas forming around filarial parasites and the cysts containing larvae of intestinal helminths. Neutrophils have been demonstrated to collaborate with macrophages in the immobilization and killing of *S. stercoralis* larvae in a process that is complement dependent and involving neutrophil extracellular traps (NETs). Similarly, neutrophils contribute in the early antifilarial response through oxidative burst, degranulation, and NETosis and protect against infective larvae in skin. A seminal study reported that neutrophils adopt an "N2" phenotype during experimental infection with *N. brasiliensis* in the lung and express the genes for IL-13, IL-33, RELM-α, and Ym1. These "N2" neutrophils can train macrophages to acquire a memory phenotype that protects against secondary infection. Finally, it was also shown that even during primary infection, the absence of neutrophils resulted in greater worm burdens because of lack of immunity in the lungs. Thus neutrophils appear to play an unexpected role in immunity to helminths that certainly merits further investigation.

PROTECTIVE IMMUNITY AGAINST HELMINTHS

The mechanism of protective immunity to helminths is dependent on the location of the helminth infection.[18] Clearly, T cells are central to resistance against helminths. For example, T cells are essential in mediating the expulsion of GI nematodes. Mice lacking T cells are defective in their ability to expel *T. muris,* but resistance can be reconstituted by transfer of T cells from normal mice. In addition, CD4 T cells from infected mice can transfer protective immunity to severe combined immunodeficiency (SCID) mice (lacking both B and T cells), indicating that CD4 T cells, not CD8 T cells, were important for protective immunity. Similarly, T cells were shown to be required for expulsion in *N. brasiliensis* infection. Both nude mice (lacking T cells alone) and SCID mice are susceptible to infection with Brugian parasites, whereas mice that lack either CD4 T cells or CD8 T cells are not. In schistosome-infected mice, T cells are essential in forming host-protective granulomas around the eggs deposited in the liver.

The role of cytokines in protective immunity has been extensively studied in murine models of both GI helminths and tissue-invasive helminths.[19] In general, type 2 (Th2) cytokines target epithelial cells, goblet cells, smooth muscle cells, and macrophages, which together coordinate parasite expulsion by increasing fluid and mucus production, encapsulation and barrier formation, epithelial cell turnover, smooth muscle cell contraction, and production of anthelmintic effector molecules, such as RELM-β. The cytokines involved in both responses are IL-4, IL-5, IL-9, and IL-13. Most of the studies examining resistance to intestinal helminths involve four parasitical GI nematode infections of rodent models—*T. spiralis, H. polygyrus bakeri, N. brasiliensis,* and *T. muris.* These studies show that *(i)* CD4 T cells are crucial for host protection; *(ii)* IL-4 is required for host protection and limiting host pathology; *(iii)* IL-13 can substitute for IL-4 in some but not all infections; *(iv)* IL-2 and IFN-γ inhibit protective immunity; and *(v)* IL-4 and IL-13 have multiple effects on the immune system and gut physiology leading generally to protection. Type 2 cytokines mobilize a broad range of downstream effector mechanisms. Epithelial cells in the gut, specifically tuft cells, promote goblet cell differentiation, enhancement of mucus secretion, and the production of RELM-β, an innate effector molecule with direct anthelmintic activity. Goblet cells can also secrete gel-forming mucins, which are major macromolecular components of the mucus barrier. Two of these mucins have been shown to be critical in resistance to intestinal nematode infection—Muc2 and Muc5AC. IL-4Rα activation also leads increased intestinal smooth muscle hypercontractility and accelerated epithelial turnover to promote an effector response akin to an "epithelial escalator," which, together with epithelial secretions, helps expel intestinal helminths. Mucosal mast cells release proteases that can degrade epithelial tight junctions, thereby increasing fluid flow as part of the "weep and sweep" response. AAMs in the gut can also entrap intestinal worms and cause death by compromising worm vitality.

Although the role of Th2 cytokines in immunity to GI helminth infection is well defined, their role in protective immunity to tissue-invasive helminths is not as clear.[18] In murine models of schistosomiasis, protective immune responses can be generated by vaccination with irradiated cercariae. This resistance is dependent on a Th1-mediated immune response consisting of macrophages and endothelial cells activated by IFN-γ and TNF-α, producing nitric oxide and Th1-associated antibodies—IgG2a and IgG2b. In contrast, studies in rats and epidemiological studies in humans suggest Th2-mediated effector mechanisms involving IgA and IgE antibodies as well as eosinophils are thought to be central to protective immunity. Protective immunity to filarial infections in mice is dependent primarily on Th2 responses in mice. Thus mice lacking IL-4, IL-4R, or Stat6 are all susceptible to infection with *Brugian* parasites.

In tissue-invasive helminth infections, effector mechanisms involve multiple innate immune cells, with antibodies acting as initiators of immunity by activating Fc receptor expressing cells. Basophils, by their ability to produce high levels of IL-4, act as effectors to promote helminth killing in secondary or challenge infections. For example, basophils are important in immunity to the skin invasive stages of intestinal helminths and, through IL-4 release, promote the activation of macrophages that trap larvae in an arginase-dependent manner. Although eosinophils are crucial players in producing IL-4 early in infection, they are also amplifiers of immune responses, rather than being critical mediators of primary immunity, since depletion of eosinophils does not alter the course of many helminth infections in murine models. The mechanism of protection mediated by eosinophils is thought to be by antibody-dependent, cell-mediated cytotoxicity, as observed in *S. mansoni* studies *in vitro* or through release of eosinophil granule contents. In addition, eosinophils play an important role in the protective immunity against primary infection with *B. malayi* and/or secondary infection with either *T. spiralis* or *N. brasiliensis.* The two most abundant granular proteins, major basic protein (MBP) and eosinophil peroxidase (EPO), are required for protective immunity against *S. stercoralis* and *L. sigmodontis.* Similarly, neutrophils can attack helminth larvae in response to IL-4 and IL-5, but their importance in resistance to primary helminth infections is not known.

Antibodies play a major role in mediating protection to some but not all helminth infections.[18] Antibody-mediated passive immunity has been demonstrated in animal models for *A. caninum,* Schistosoma species, Taenia species, *Ascaris suum, S. ratti, T. muris, N. brasiliensis,* and *H. polygyrus bakeri.* Passive immunity has also been shown by using IgG monoclonal antibodies (mAbs) specific for *Fasciola hepatica* and *S. mansoni;* IgM (mAbs) specific for *B. malayi;* and IgG or IgA mAbs specific for *T. spiralis.* Again using genetically manipulated mouse models, IgM has been shown to be crucial for host protection against *B. malayi* and to *S. stercoralis.* B1B cells, a subset of B cells that secrete IgM, appear to be an important component of this protective axis. Finally, antibodies have the capacity to trap tissue migrating helminth larvae and prevent tissue damage by driving an IL-4Rα–independent alternative differentiation of macrophages, in a process dependent on CD11b and FcγR1.

In terms of protection, a major mechanism appears to be the formation of multicellular, immune cell aggregates, called *granulomas,* around incoming infectious larvae or eggs.[18] In murine models of schistosomiasis and filariasis, granulomas are primarily composed of T cells (which help in the recruitment of other cell types and mediate alternative activation of macrophages), B cells (particularly the B1 subset), and macrophages and eosinophils. Although the exact mechanism by which granulomas mediate killing of the parasite remains unknown, it is clear that formation of these structures is an important host defense mechanism. One cell type that can mediate effector functions within granulomas

KEY CONCEPTS

Helminth-Induced Immune Responses

Characterized by immunoglobulin E (IgE) antibody production, tissue and peripheral blood eosinophilia, mast cell involvement, innate lymphoid cell type 2 and Th2 cell expansion, and production of type 2 cytokines.

Implicated both in pathogenesis of helminth infections and in mediating immunological protection.

In mucosal immunity to helminths, T-helper 2 (Th2) cell responses are initiated and sustained by innate populations (including tuft cells and innate lymphoid cells) through interleukin (IL)-25, IL-33, and thymic stromal lymphopoietin (TSLP).

In tissues, helminths are acted upon by the host innate effectors, including macrophages, neutrophils, eosinophils, and basophils.

Regulated by T cells and other cells producing IL-4, IL-5, IL-9, IL-10, and/or IL-13.

Characterized by the induction of regulatory T cells (Tregs) that mediate downmodulation of immune responses to helminth infections and impact bystander phenomena, such as allergy and autoimmunity.

is the AAM, which is exemplified by the targeting of the glycan chitin that is frequently expressed by helminths but not by the host. The chitinase and fizz family proteins (ChaFFs), which include chitinase and chitinase-like secreted proteins, are prime candidates for mediating host resistance. These proteins include acidic mammalian chitinase (AMCase) and the RELM family proteins and are capable of enzymatic activities that potentially damage certain helminths.

PATHOLOGY ASSOCIATED WITH IMMUNE RESPONSES IN PARASITIC HELMINTH INFECTION

Typically, pathological findings associated with each parasitic infection are different and relate to the presence of the parasites in host tissues, but there are pathological reactions that stem directly from the host response.

Immune Complexes

Immune complexes are potent mediators of localized inflammatory processes that form in many parasitic infections presumably as a result of the chronic low-dose antigen release seen in these infections. Circulating immune complexes have been identified in both experimental and human filarial and schistosomal infections. These have been shown to induce lymphatic inflammation and vasculitis in filarial infections as a result of their deposition. In addition, a common manifestation of immune complex–mediated pathology, immune complex glomerulonephritis (ICGN), has been documented by renal biopsy in patients with schistosomiasis and filarial infections. Other manifestations of immune complex–mediated damage, such as reactive arthritis and dermatitis, have also been described in patients with helminth infections.

Autoantibodies and Molecular Mimicry

Autoantibodies have been implicated as causing disease in a variety of helminth infections, including filarial infections, schistosomiasis, and hookworm infection, and are thought to reflect a polyclonal B cell expansion that often accompanies these infections.[20] Autoantibodies against nuclear material have been found in a vast majority of patients with chronic schistosomiasis, and antibodies against human calreticulin and defensin have been found in onchocerciasis.

Granulomatous Reactions

Granuloma formation is the mainstay of the protective immune response to certain helminths, but it can also lead to deleterious effects in the form of pathology. Although granulomatous reactions occur in many helminth infections (*e.g.,* toxocariasis, *Angiostrongylus* infections and lymphatic filariasis), parasitical granulomata have been best studied in *S. mansoni* infections, where granulomatous and fibrosing reactions against tissue-trapped eggs is orchestrated by CD4 T cells and the fibrosis that results from the cellular response is the principal cause of morbidity in infected individuals. The severity of the inflammatory process markedly varies both in humans and in experimental animal models, with severe pathology associated with Th1 and Th17 responses and milder pathology with Th2-dominant responses.[21] Studies in murine models of granuloma formation have demonstrated the important roles of IL-13 and TNF-α.

Fibrosis

Fibrosis is commonly associated with chronic helminth infections that result in chronic inflammation and dysregulated wound healing.[22] These infections activate macrophages and fibroblasts, resulting in the production of TGF-β, platelet-derived growth factor (PDGF), IL-1β, and other factors. Macrophages also promote inflammation by recruiting and activating monocytes and neutrophils, as well as activating CD4 T cells. In addition, fibroblasts are stimulated to synthesize matrix metalloproteinases (MMPs) and tissue inhibitors of metalloproteinases (TIMPs), leading to extracellular matrix remodeling and fibrosis. Another consequence of chronic schistosomiasis is pulmonary arterial hypertension, which has been shown to be associated with IL-4– and IL-13–mediated type 2 inflammation resulting in TGF-β–induced pulmonary vascular disease. In the same manner, IL-10 and IL-12 are known to modulate IL-13–mediated fibrosis; in the combined absence of IL-10, IL-12, and IL-13Rα, IL-13–dependent fibrosis in chronic schistosomiasis proceeds rapidly to lethal cirrhosis. Infection with *Wuchereria bancrofti* (one of the causative agents of lymphatic filariasis) is associated with similar fibrotic reactions.

Toll-Like Receptors

Immunopathology in lymphatic filariasis is associated with the presence of an endosymbiotic, *Rickettsia*-like bacteria called *Wolbachia. Wolbachia* are known to stimulate immune cells through TLR2 and TLR4 and release proinflammatory cytokines, as well as vascular endothelial growth factors (VEGFs), which might contribute to lymphatic pathology.[23] *Wolbachia*-TLR4 interaction has also been shown to be the major mechanism of corneal inflammation in onchocerciasis, and a TLR signaling molecule, IL-1 receptor associated kinase-2 (IRAK-2), regulates pathogenic Th17-cell development in *S. mansoni* infection.

Immediate Hypersensitivity Responses

Immediate hypersensitivity responses are associated with the early and/or acute phase of infections with invasive helminth parasites, such as *Ascaris,* hookworm, schistosomes, or filariae. Patients do manifest symptoms suggestive of allergic reactivity, such as wheezing or urticaria. Furthermore, in clinical syndromes associated with *Loa loa* infection (with its angioedematous Calabar swellings), with tropical pulmonary eosinophilia, and with larva currens in strongyloidiasis, IgE-mediated reactions are thought to underlie these signs and symptoms.[24] Anaphylaxis is a severe, life-threatening, generalized, or systemic hypersensitivity reaction, and is associated with IgE interaction with high-affinity IgE receptors on basophils and mast cells (Chapter 23). The risk of anaphylaxis in individuals with helminth infections can vary, depending on the parasite, tending to occur more frequently with echinococcosis or after Anisakis infection, while being extremely rare in most other helminth infections.

Wound Healing

Recent studies have shown a close association of type 2 cytokine responses with many aspects of wound healing and repair.[25,26] It has been proposed that the type 2 cytokine response has evolved to not only mediate resistance to helminth infection but also activate the wound healing apparatus to repair and reconstruct tissue, since tissue damage is intricately associated with helminth infections. Thus AAMs are intimately involved in this process as they produce MMPs, Arginase-1, insulin-like growth factor 1 (IGF1), VEGF, and TGF-β, which together promote myofibroblast activation, angiogenesis, epithelial cell turnover, and extracellular matrix deposition.

Lymphangiogenesis

The anatomical changes in the architecture of lymphatics, which range from lymphangiectasia and granulomatous responses to the development of collaterals, suggest that active lymphatic remodeling involving endothelial cell growth, migration, and proliferation is an important feature of early lymphatic filarial disease. Live filarial parasites (and their excretory/secretory products) have been shown to induce activation, proliferation, and tube formation in lymphatic endothelial cells (LECs) and their differentiation into tubelike networks.[27] This was found to be associated with significantly increased levels of MMPs and TIMPs. Recent studies have also implicated the VEGF family in lymphangiogenesis, with VEGF-C being associated with lymphedema and VEGF-A with hydrocele.[23] Finally, TLR-mediated events are considered to be the main drivers of this angiogenic/lymphangiogenic process in filarial disease.[27]

Carcinogenesis

Infection with *Opisthorchis viverrini, Clonorchis sinensis,* and *Schistosoma hematobium* are classified as group 1 biological carcinogens (*i.e.,* definitive causes of cancer). The former (liver fluke) is associated with cancer of the bile duct (cholangiocarcinoma) and cancer of the liver (hepatocarcinoma), and the latter is associated with carcinoma of the urinary bladder. The mechanisms of helminth-induced cancer include chronic inflammation, sustained cellular proliferation, modulation of the host immune system, reprogramming of glucose metabolism and redox signaling, induction of genomic instability and destabilization of tumor proteins, stimulation of angiogenesis, resistance to apoptosis, and activation of invasion and metastasis.[28]

Epileptogenesis

Neurocysticercosis, caused by the larval form of *Taenia solium,* is the most common preventable risk factor for epilepsy worldwide and accounts for nearly 30% of all epilepsies in some endemic areas. The manifestations are variable, depending on the location, number, and size of the cysts in the central nervous system as well as the degree of accompanying inflammation, provoked by cyst degeneration, calcification, and/or perilesional edema.

MECHANISMS OF EVASION AND IMMUNE REGULATION BY HELMINTH PARASITES

Helminths exert profound immunoregulatory effects on the host immune system with parasite antigen–specific immune suppression as well as more generalized levels of immune suppression. It has been shown that patients with schistosomiasis or filariasis have markedly diminished responses to parasite antigens and to some measurable attenuation in responses to bystander antigens and routine vaccinations. Thus host immunosuppression is usually antigen specific, whereas chronic infection can be associated with some spillover effects. Among the mechanisms utilized by parasites to avoid immune-mediated elimination are those of evasion—the use of sequestration, camouflage, and antigenic variation—and suppression, regulation, or blockade of immune effector pathways.

Parasite-Derived Factors

Parasite-derived products play a very important role in host immune evasion.[29,30] Parasite products, such as the schistosome-secreted proteins, alpha-1 and omega-1, promote Th2 differentiation. Alpha-1 (also known as IL-4–inducing principle of schistosome eggs [IPSE]), released by schistosome eggs, induces IL-4 release and degranulation by human and mouse basophils by cross-linking surface IgE. Omega-1 is a ribonuclease abundantly secreted by eggs, shown to condition DCs to drive Th2 polarization. Omega-1 binds to and is internalized by DCs in a mannose receptor–dependent process and then suppresses protein synthesis through degradation of messenger RNA (mRNA).

Phosphorylcholine (PC) is a small hapten-like moiety present in the excretory/secretory products of many helminths, and one particular PC-containing molecule, called ES-62, from filarial worms has been shown to have a wide variety of immunomodulatory properties. Thus ES-62 can inhibit the proliferation of CD4 T cells and conventional B cells, decrease IL-4 and IFN-γ production, promote proliferation and IL-10 production by B1B cells, modulate complement activation, and condition APCs to drive Th2 differentiation with concomitant inhibition of Th1 responses. ES-62 has also been shown to exhibit bystander antiinflammatory activity in collagen-induced arthritis, rheumatoid arthritis, chemical contact sensitivity, lupus-associated atherosclerosis, ear inflammation, chronic asthma, and airway hyperreactivity. Helminths utilize glycans within glycoproteins and glycolipids, which mimic host glycans, to regulate host immune responses. In addition, these host-like helminth glycans can directly interact with host glycan–binding proteins, such as C-type lectin receptors and galectins, to shape innate and adaptive immune responses. Similarly, helminth lipids have also been implicated in immune modulation; schistosome phosphatidylserine induces DCs to polarize IL-4–producing T cells, whereas schistosome lysophosphatidyl serine induces DCs to induce IL-10–secreting Tregs.

Helminth parasites utilize mechanisms involving cytokine mimicry and interference to establish chronic infection. Thus parasites produce cytokine- and chemokine-like molecules to interfere with the function of host innate immune products. The first helminth cytokines were found to be homologues of TGF-β expressed by *B. malayi*, and both schistosomes and filarial parasites express members of the TGF-β receptor family. Similarly, *E. granulosus* expresses a TGF-β ligand, and thus all helminth groups might have the potential to exploit TGF-β–mediated immune suppression. Various helminths, including *B. malayi*, produce homologues of macrophage migration inhibitory factors

(MIFs), which are known to activate an antiinflammatory pathway through SOCS-1, a molecule involved in cytokine signaling. *T. muris* is known to express a homologue of IFN-γ, which binds to the IFN-γ receptor *in vitro* and induces signaling. As *T. muris* is expelled by IL-4, secretion of an IFN-γ–like protein can prolong its survival.

Similarly, helminth parasites utilize chemokine- or chemokine-receptor like proteins to evade protective immunity. *Ascaris suum* is known to express a neutrophil chemoattractant with chemokine binding properties. *S. mansoni* eggs secrete a protein (*S. mansoni* chemokine-binding protein [smCKBP]) that binds the chemokines CXCL8 and CCL3 and inhibits their interaction with host chemokine receptors and their biological activity, resulting in suppression of inflammation.[31] Similarly, *B. malayi* (and all of the other filariae sequenced to date) has been shown to express galectins that can bind host immune cells in a carbohydrate-dependent manner.

Helminths secrete two major classes of protease inhibitors called *cystatins* and *serpins,* each with proposed immunomodulatory roles. Cystatins inhibit cysteine proteases (cathepsins and aspartyl endopeptidases) required for antigen processing and presentation and therefore inhibit T-cell activation. They also elicit the regulatory cytokine IL-10, leading to direct impairment of T-cell proliferation. The serpins are serine protease inhibitors, which can cause specific inhibition of the neutrophil proteinases cathepsin G and neutrophil elastase. Aspartic proteases from *Ascaris lumbricoides* have been shown to block efficient antigen processing that is dependent on proteolytic lysosomal enzymes.

Other parasite products mediate their effect by blocking effector functions, including recruitment and activation of inflammatory cells and limiting the destructive potential of activated granulocytes or macrophages in the local extracellular milieu. For example, the host chemoattractant platelet-activating factor (PAF) is inactivated by a complementary enzyme PAF hydrolase secreted by *N. brasiliensis.* Eotaxin-1, a potent eosinophil chemoattractant, is degraded by metalloproteases from hookworms. *A. caninum* secretes a protein called *neutrophil inhibitory factor,* which binds the integrins CD11b/CD18 and blocks adhesion of activated neutrophils to vascular endothelial cells and also the release of hydrogen peroxide (H_2O_2) from activated neutrophils. *N. americanus* ES products also bind to host NK cells and augment the secretion of IFN-γ, which might cross-regulate deleterious Th2 responses. Other modulators, such as prostaglandins, and other arachidonic acid family members, such as PGE2 and PGD2, are known to inhibit IL-12 production by DCs. Finally, helminths susceptible to oxidant-mediated killing express both secreted and membrane-associated enzymes, such as superoxide dismutase, glutathione-S-transferase, and glutathione peroxidase, molecules that are thought to play a significant role in assisting parasite survival in inflamed tissues. Recently, a family of helminth defense molecules secreted by parasitic helminths has been shown to exhibit biochemical and functional characteristics similar to human antimicrobial peptides. These molecules can modulate innate cell activation by classic TLR ligands, such as lipopolysaccharide.

It has been also been reported that parasitical helminths can produce exosomes and other secretory vesicles that facilitate the transfer of intracellular cargo. Exosomes derived from helminths have been shown to possess immunomodulatory capacity with the ability to modulate immune responses by altering the function of ILC2. In addition, secreted vesicles from *B. malayi, O. volvulus,* and *S. mansoni* have been shown to contain microRNAs that can then act as messengers of communication between the parasite and the host cell. These exosomes (containing microRNA) can then enter the host cell and modulate host gene expression.[32]

Host-Related Factors

Regulatory T and B Cells

Evidence for the involvement of Tregs in helminth-mediated downmodulation of the immune response has been accumulating in recent years[33] (Chapter 18). IL-10 and TGF-β, both factors associated with Tregs, are elicited in response to helminth infections, and *in vitro* neutralization of IL-10 and TGF-β at least partially restores T-cell proliferation and cytokine production in lymphatic filariasis. Similar reversals of immunosuppression are observed in onchocerciasis and schistosomiasis, with IL-10 producing natural Tregs (nTregs) from egg-induced granulomas (in *S. mansoni* infection) being important for host survival. More recently, Tregs from patients with filarial infections have also been shown to express high levels of other suppressive molecules, such as CCL4, IL-29, LAG-3, and Foxo3. Moreover, filarial infection is associated with an expansion of T cells expressing the IL-10 superfamily cytokine members (IL-19 and IL-24), and inhibition of these cytokines results in increased Th1 and Th2 responses. Tregs play a vital role in limiting host pathology by downregulating harmful Th1/Th17 responses in filarial infection and schistosomiasis. In addition, low level Treg activity is essential for type 2 effector immunity to expel certain intestinal helminths, and transdifferentiation of Th17 cells into Tregs during helminth infection is important for resolution of inflammation.

A number of studies have recently reported that B cells might have an active regulatory role in helminth infections. For example, purified B cells from mice infected with *B. malayi* produce IL-10 in response to filarial antigens. Similarly, IL-10 producing $CD1d^{hi}$ B cells are induced in both mice and humans and are suppressed after anthelmintic treatment. This induction occurs, in part, through a mechanism involving the ICOS-B7RP-1 pathway.

Hyporesponsive T Cells

Effector T cell responses can be turned off or modulated through a variety of mechanisms, including through cytotoxic T lymphocyte antigen-4 (CTLA-4) and programmed death-1 (PD-1). Interestingly, increased expression of CTLA-4 and PD-1 has been demonstrated in filarial infections, and blocking of CTLA-4 can partially restore a degree of immunological responsiveness in cells from infected individuals. Moreover, T cells have decreased induction of *T-bet,* the Th1 master regulatory gene indicating a failure at the transcriptional level to differentiate into Th1 cells. Finally, T cells from individuals with filarial infection exhibit classic signs of anergy, including diminished T-cell proliferation to parasite antigens, lack of IL-2 production, and increased expression of E3 ubiquitin ligases. Similarly, anergic T cells are found in both humans and mice with *F. hepatica* infection and schistosomiasis; in the latter case, these T cells express high levels of the anergy molecule GRAIL (gene related to anergy in lymphocytes).

Modulation of Apc Function

DCs are the first APCs usually to encounter parasites, and helminth modulation of DC function has been well characterized.[34] Filarial parasites induce downregulation of MHC class I and class II molecules, as well as cytokines and other genes involved in antigen presentation, thereby rendering DCs suboptimal in their ability to activate CD4 T cells. Schistosomes have similar effects on DCs, with subsequent Th2 polarization and inhibited responses to Th1-inducing TLR ligands. In addition, schistosomes modulate the activation of Nlrp3 (NLR family, pyrin domain containing 3) inflammasome and thus IL-β production. Excretory/secretory antigens produced by helminths can inhibit DC synthesis of proinflammatory cytokines, chemokines, and costimulatory molecules and promote DC production of the regulatory cytokines IL-10 and TGF-β. Helminth infection has also been shown to induce *in vivo* differentiation of a $CD103^-$ $CD11c^{lo}$ population of regulatory DCs, which are inefficient in priming effector T cells and instead favor the generation of Tregs. AAMs are able to markedly suppress target cell proliferation, as well as mediate repair of tissue that has been damaged by parasites. In addition, human filarial infection is associated with the expansion of the nonclassic monocyte subset, as well as an immunoregulatory monocyte subset. Helminth antigens can modulate MHC class II and CD80/86 expression on "antigen-presenting" basophils to induce the development of Th2 cells. Finally, a heterogeneous population of immature myeloid cells that share the common property of suppressing immune responses are termed *myeloid-derived suppressor cells* (MDSCs). Although these MDSCs have been well characterized in cancer immunology, their role in helminth infections is still being explored.

Apoptosis

Another mechanism of immune evasion is the ability of some helminths to induce host cell apoptosis (Chapter 13). Apoptosis has been described as a host regulatory mechanism in various helminth infections, including schistosomiasis, lymphatic filariasis, and onchocerciasis.

HELMINTHS AND THE MICROBIOTA

Recent work has highlighted the importance of the microbiota in influencing host immunological and metabolic functions (Chapter 14). Helminths secrete a variety of products that can directly influence the composition and function of the microbiota, whereas changes in microbiota can have an impact on susceptibility to helminth infection, indicating that helminth–microbiota cross-talk can regulate a variety of host processes.[35] Recently, it was reported that infection with helminths (*H. polygyrus* or *T. muris*) results in alteration of the composition of the microbiota, with expansion of Lactobacillacea and Enterobacteriacea in the gut, and that the removal of helminths resulted in restoration of the original composition of the microbiota. The consensus in humans is yet to emerge, with some studies showing an effect of helminth infection on microbial diversity and others failing to reveal any differences. Conversely, it has also been demonstrated that introducing higher level of certain commensal microbes enhances susceptibility, whereas removal of microbiota by antibiotics decreases susceptibility to helminth infections.

REGULATION OF ALLERGY, AUTOIMMUNITY, AND METABOLIC DISEASES IN HELMINTH INFECTION

The hygiene hypothesis postulates that the stimulation of the immune system by microbes or microbial products protects from the development of inflammatory and atopic disorders[36] (Chapter 1). Human studies have demonstrated that people living in areas endemic for helminth infections have a decreased reactivity to skin tests for allergens and milder forms of asthma.[37] Experimental animal models have revealed the protective effect of helminth infections against atopy and asthma. Several mechanisms have been proposed for the helminth-induced protection, the chief of which are the induction of Treg activity, regulatory B-cell activity, and immunosuppressive cytokines including IL-10 and TGF-β. Similarly, exposure to helminth parasites has been shown to prevent the onset of Th1-mediated diseases, such as multiple sclerosis (MS), diabetes mellitus, and Crohn disease in experimental animal models.[37] Finally, recent studies in mice have shown that type 2 immunity, induced by helminth infection, can maintain adipose tissue homeostasis and promote adipose tissue beiging, protecting against obesity and metabolic dysfunction; that the immunomodulatory glycan LNFPIII, which is secreted by helminths, can alleviate hepatosteatosis and insulin resistance; and that there exists an inverse association between the presence of helminth infections and the prevalence of type 2 diabetes.

HELMINTH THERAPY FOR INFLAMMATORY DISEASES

To date, two species of helminths have been tested as clinical treatment for therapy of inflammatory diseases: *T. suis* ova and infection with *N. americanus*. Currently, 28 clinical trials of helminth therapy in 10 autoimmune diseases and allergic or related conditions have been planned, started, or completed.[38] These include Crohn disease, ulcerative colitis, MS, celiac disease, autism, plaque psoriasis, peanut and tree nut allergy, asthma, rhinoconjunctivitis, and rheumatoid arthritis. Although well tolerated, recent results suggested that this therapy did not achieve improvement in disease activity or remission rates in Crohn disease. Studies using *N. americanus* include fairly small trials with patients with Crohn disease or individuals with celiac disease (gluten allergy). Additionally, a few studies have been performed examining the effect of helminth therapy on asthma/allergy. The one minor success of helminth therapy in humans is in the treatment of MS, wherein small trials have successfully demonstrated lower relapses and lower magnetic resonance imaging (MRI) activity, prompting larger phase I or II trial involving either *T. suis* or *N. americanus*.

ON THE HORIZON

- Identification and synthesis of helminth products that can be useful as immune therapy in a variety of inflammatory disorders
- Deciphering the three way cross-talk among host immunity, helminths, and the microbiota
- Elucidation of the detailed mechanisms by which helminths manipulate immune responses to bystander antigens
- Development of clues to production of novel vaccine candidates to protect against not only helminth infection but also helminth-induced morbidity
- Combined approaches involving genomics, transcriptomics, proteomics, and metabolomics for assessment of host–helminth interactions

VACCINES AGAINST HELMINTH PARASITES

Vaccines against helminth infections are a necessary tool for their elimination and eradication for several different reasons.[39] Currently, a total of five human anthelmintic vaccines have advanced from discovery through manufacture and are now in phase I or II clinical testing.[40] These include three Schistosome vaccine candidates: *(i) S. hematobium* Sh28GST (phase II); *(ii) S. mansoni* Sm-TSP-2 (phase I); *(iii) S. mansoni* Sm-14 (phase I); and two hookworm vaccine candidates: *(i)* Na-GST-1 (phase I); *(ii)* Na-APR-1 (phase I). In addition, the two *O. volvulus* vaccine candidates—Ov-103 and Ov-RAL2—and the *S. mansoni* candidate—Sm-p80—are in preclinical testing. With rapid advances in the parasite genomics and proteomics, as well the newer, better vaccine delivery systems offering more efficient and quicker assessment, the prospects for newer anthelmintic vaccines are excellent, although the potential lack of commercial markets imposes a significant impediment to their development.

MULTIPLE-CHOICE QUESTIONS

1. The immunity to helminths typically involves a T-helper 2 (Th2) cell response with what other component of the T-cell response?
   A. Th1 response
   B. Th17 response
   C. Regulatory T-cell response
   D. Th22 response

2. The classic antibody isotypes induced by helminths typically include:
   A. Immunoglobulin E (IgE) and IgG4
   B. IgE and IgG3
   C. IgE and IgD
   D. IgG1 and IgG2

3. These cells are a novel cell type recently shown to play a pivotal role in the initiation of immunity to helminth parasites:
   A. Natural killer (NK) cells
   B. Type 1 innate lymphoid cells
   C. Type 2 innate lymphoid cells
   D. Type 3 innate lymphoid cells

32

Approach to the Evaluation of the Patient With Suspected Immunodeficiency

Javier Chinen, Mary E. Paul, William T. Shearer

KEY CONCEPTS

Secondary Immunodeficiencies

Immunodeficiency is often secondary or transient, caused by nonimmune factors, including:

- Previous use of high-dose steroids, or other immunosuppressive medications
- Previous use of monoclonal antibodies (mAbs), such as rituximab (anti-CD20)
- Immunoglobulin losses via the gastrointestinal or urinary tract
- Severe illness requiring critical care
- Malnutrition
- Human immunodeficiency virus (HIV) infection

Clinical immunologists are often consulted to evaluate patients for suspected immune defects, usually because such patients have an unusual frequency or severity of infectious illnesses. Indeed, immunodeficiency presents with increased susceptibility to infection but may also manifest with conditions that reflect dysregulation of the immune response, such as allergies, autoimmunity, or lymphoproliferation. Prompt diagnosis is essential to reduce the risk of organ damage caused by preventable severe infections. Primary immunodeficiencies (PIDs) are congenital diseases that might affect any aspect of the immune response and are often diagnosed in childhood. Examples of PIDs include severe combined immune deficiencies (SCIDs), complete DiGeorge syndrome, and chronic granulomatous disease (CGD). In contrast to PIDs, secondary immunodeficiencies (Chapters 38, 39) present at any age, as a result of a wide variety of factors that affect the immune function, such as environmental factors, metabolic disease, anatomical abnormalities, or infectious agents. The most known and significant secondary immunodeficiency is caused by human immunodeficiency virus (HIV). The assessment of a patient for PID should include history and physical examination to direct immunology laboratory testing to confirm a diagnosis.

EPIDEMIOLOGY—PRIMARY IMMUNODEFICIENCIES ARE NOT UNCOMMON

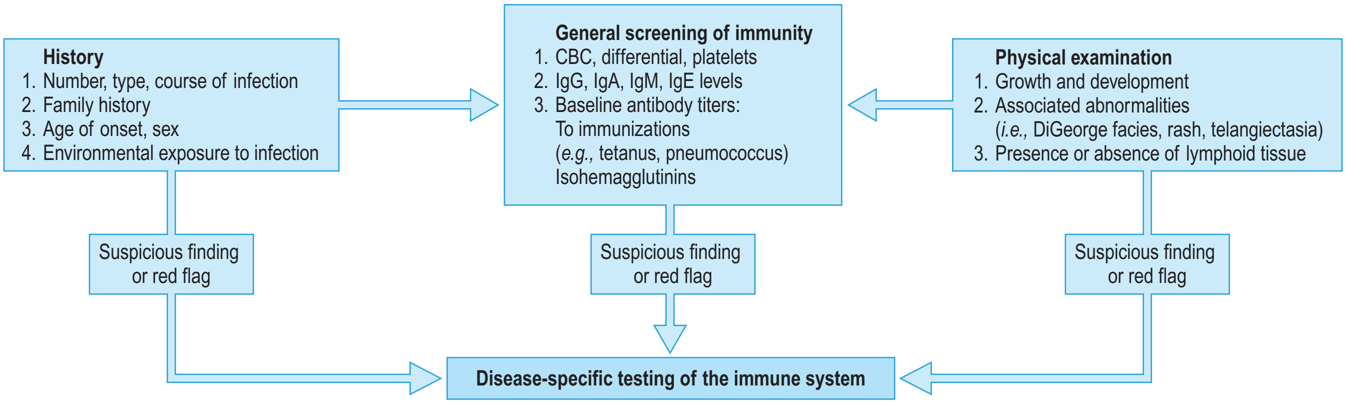
Estimates of the incidence of PIDs or congenital immunodeficiencies varies from selective immunoglobulin A (IgA) deficiency, a relatively common condition, (1/223–1/1000 people)[1] to the less common SCID. Recent analysis from 11 state programs established for universal newborn screening for T-cell deficiencies in the United States reported an incidence of SCID of 1/58 000 live births, comparable with childhood leukemia.[2] A household-based telephone survey suggested that 1 in 1200 persons in the United States has been diagnosed with a PID.[3] Although significant progress has been made to stop the acquired immunodeficiency syndrome (AIDS) epidemic, HIV infection continues to be the most prevalent cause of immunodeficiency worldwide, with an estimated 36.9 million people living with HIV.[4]

PRIMARY VERSUS SECONDARY IMMUNODEFICIENCY

Because of their common occurrence, acquired and nonimmunological causes for recurrent infections should be first considered in the differential diagnosis of the patient with a suspected immune disorder. Acquired conditions that might increase the frequency of infections include allergic inflammation, HIV infection, and the use of immunosuppressive drugs. Examples of nonimmunological conditions include those that disrupt the usual mucosal clearance mechanisms, such as posterior urethral valves or urethral stenosis in a patient with recurrent urinary tract infection, or cystic fibrosis in individuals who have recurrent sinusitis or pneumonia and/or diarrhea. Disruption of natural barriers can lead to increased risk of infection, for example, in patients with skin lesions caused by eczema or burns or in individuals with cerebrospinal fluid (CSF) leaks following bony injury to the cranium. Patients presenting with low Ig levels might have loss of antibodies as a result of a protein-losing enteropathy, nephropathy, or massive protein loss through skin, such as in severe eczema or burns.[5] Secondary immunodeficiency can also result from other conditions affecting cell metabolism (*e.g.*, malnutrition, diabetes mellitus, and sickle cell anemia) or could be secondary to predictable or idiopathic adverse effects of drugs. Optimal management of these conditions often results in improved immunity.

EVALUATING PATIENTS FOR IMMUNODEFICIENCY

The evaluation of patients for immunodeficiency is based on a careful assessment of patient history and physical examination, with very limited initial laboratory testing. With this information, the clinician can often tell patients (or parents) whether their (or their child's) immune system is significantly compromised. The immunologist must take on a role of counselor and advisor of patients and explain the many factors that may result in increased frequency of infections (Fig. 32.1). The limitations of available clinically validated testing need to be considered, as such tests may not be sensitive or specific to identify uncommon



History
1. Number, type, course of infection
2. Family history
3. Age of onset, sex
4. Environmental exposure to infection
General screening of immunity
1. CBC, differential, platelets
2. IgG, IgA, IgM, IgE levels
3. Baseline antibody titers:
To immunizations
(e.g., tetanus, pneumococcus)
Isohemagglutinins
Physical examination
1. Growth and development
2. Associated abnormalities
(i.e., DiGeorge facies, rash, telangiectasia)
3. Presence or absence of lymphoid tissue
Suspicious finding or red flag
Suspicious finding or red flag
Suspicious finding or red flag
Disease-specific testing of the immune system

FIG 32.1 **Evaluation of Immunity in a Patient for Immunodeficiency Starts With a Careful History and Physical Examination.** Clues in the history for further evaluation include an excess of respiratory tract infections, of unusual severity; life-threatening infections; infections with unusual organisms; a family history of immunodeficiency. The outlined laboratory tests provide an adequate screen of immunity in a patient with no specific findings.

immune defects, such as impairments in phagocyte function other than oxidative burst deficiency. The medical history and initial laboratory testing often provide clues that suggest a specific immune disorder, and the examination of specific component of the immune response or a diagnostic test for specific immunodeficiencies may be indicated. For example, an increased frequency of infections affecting only the respiratory tract and caused by encapsulated bacteria direct the exploration to defects in humoral immunity and complement; in contrast, a history of *Aspergillus* pneumonia would suggest neutropenia and CGD. According to the severity of the illness, clinical immunologists may recommend an initial exploration of the major components of the immune system: lymphocyte subset distribution, antibody responses, T-cell function, phagocyte oxidative burst, and the complement system.

EXPLORING THE MEDICAL HISTORY

Age and Environment

The differential diagnosis of immunodeficiency varies with the age of onset of symptoms. Pediatric patients are more likely to present a PID than a secondary immunodeficiency. Infants from birth to 3 months of age have maternal Igs acquired through the placenta, unless they were born prematurely. Therefore deficiencies in the immune system at this age presenting with frequent infections most probably result from severe deficiencies in other immune components, such as neutrophils, complement components, or T cells. Older patients might present with increased risk of infections secondary to comorbid conditions, such as allergic inflammation or diabetes mellitus, or to a normal decline of immune responses, a process known as *immunosenescence* (Chapter 38).[6] Environmental conditions can influence the risk of infection. Infants frequently exposed to other infants with infections, such as in the setting of a daycare facility, have more infectious illnesses compared with those who are not exposed. By inducing an inflammatory response of the respiratory mucosa, passive cigarette smoke inhalation also predisposes to infections, including otitis media, pneumonia, and bronchitis.[7] The hygiene practices of the patient, caregivers, and family members have an impact on the frequency of infections, such as impetigo and furunculosis. For patients with allergies, exposure to indoor allergens, such as dust mites and molds, often worsens mucosal congestion and increases the risk of sinusitis and otitis media.

Immunization and Previous Infections

The immunization history provides significant clues, since the efficacy of vaccines depends on intact immunity. An incomplete schedule of immunizations easily explains the incidence of preventable diseases. A history of an adverse reaction to a live viral vaccine is suspicious for immunodeficiency, as infants with T-cell defects, B-cell defects, and combined T- and B-cell defects are susceptible to potentially fatal or severe infections from live attenuated vaccines. These infections include measles and chicken pox pneumonitis, rotavirus vaccine-induced diarrhea,[8] and lymphadenitis caused by the Bacille Calmette-Guérin (BCG) vaccine.[9] Historical information regarding the frequency, type, and severity of illnesses and infections should be sought. Individuals with immunodeficiency may have infections with unusually prolonged courses or unusual severity or that may present as unexpected complications (Fig. 32.2). Recurrent infections that involve multiple sites are more suspicious for immune deficiency than those involving a single site. Also suggestive of immune compromise are severe and invasive infections, such as recurrent pneumonia, meningitis, sepsis, septic arthritis, osteomyelitis, or abscess and infections with organisms of low pathogenicity in normal individuals, such as *Candida albicans* or *Pneumocystis jiroveci* (Table 32.1) Patients with antibody deficiency disorders tend to present with infections caused by extracellular pyogenic organisms, such as *Haemophilus* spp., *Pneumococcus* spp., and *Streptococcus* spp. In contrast, patients with defects in cell-mediated immunity are more likely to also present with recurrent infections with viruses, fungi, protozoa, and mycobacteria. Furthermore, infections by catalase-positive bacteria, such as *Serratia marcescens,* may indicate a possible neutrophil oxidative burst defect. Recurrent neisserial infections may be found in individuals deficient in the terminal complement components. A relatively normal incidence of infections followed by a sudden occurrence of repeated infections in an adult or adolescent suggests a secondary immunodeficiency, including HIV infection.

TABLE 32.1 Clinical Clues of Significance for the Diagnosis of Immunodeficiencies

	T-Cell Function Defect	Antibody Defect	Granulocyte Defects	Complement Defect	IFN-γ/IL-12 Defect
Recurrent or severe bacterial infections	X	X	X (catalase-positive)	X (encapsulated bacteria)	
Systemic mycobacterial infections	X				X
Recurrent or severe viral infections	X	X	X		X
Invasive fungal infections	X		X		
Opportunistic infections	X		X		X
Failure to thrive	X	X	X		
Autoimmunity	X	X	X	X	
Lymphoma	X	X (CVID)			

CVID, common variable immunodeficiency; IFN, interferon; IL, interleukin.

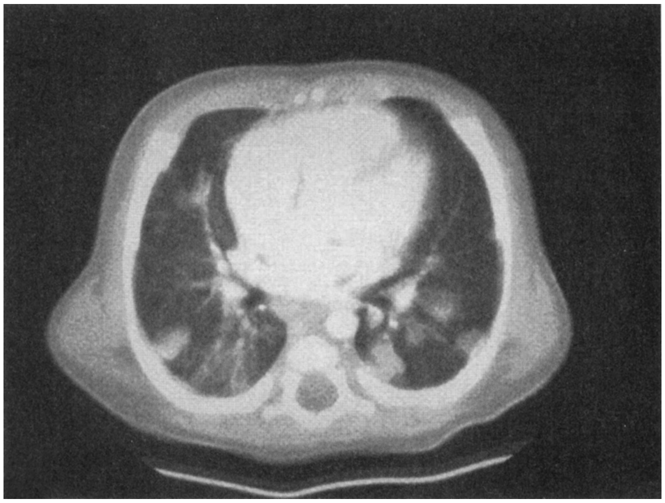


FIG 32.2 **Computed Tomography (CT) Scan in an Infant With Chronic Granulomatous Disease (CGD).** Multiple nodular opacities are seen throughout both lung fields as a result of fungal pneumonia in an infant with CGD. (From Seeborg FO, et al. A 5-week-old HIV-1-exposed girl with failure to thrive and diffuse nodular pulmonary infiltrates. J Allergy Clin Immunol 2004; 113: 629, with permission from Elsevier.)

TABLE 32.2 Nonimmunological Clinical Findings Present in Immunodeficiency Syndromes

Nonimmunological Clinical Finding	Immunodeficiency
Small platelets, thrombocytopenia, eczema	Wiskott-Aldrich syndrome (WAS)
Conical teeth, ectodermal dysplasia	Nuclear factor κB (NF-κB) essential modulator (NEMO) defect
Delayed shedding of primary teeth, frequent fractures, hyperextensibility	Autosomal dominant hyper-IgE syndrome (AD-HIES)
Cerebellar ataxia, telangiectasia	Ataxia–telangiectasia (AT)
Hypoparathyroidism, conotruncal heart defect, velopalatal insufficiency	DiGeorge syndrome
Short limbs	Cartilage-hair hypoplasia
Microcephaly	DNAse IV–deficient severe combined immunodeficiency (SCID), Nijmegen syndrome
Silvery hair, albinism	Pigment dilution disorders
Pectum carinatum, skeletal dysostosis, pancreatic insufficiency	Shwachman-Bodian-Diamond syndrome (SBDS)

Comorbid Conditions

Apart from frequent infections, other important aspects of the history and physical examination may suggest congenital syndromes associated with immune defects (Table 32.2). Neutrophil adhesion defects lead to delayed (beyond 2 weeks of age) umbilical cord separation because of omphalitis and poor wound healing. Patients with DiGeorge syndrome are usually diagnosed in the neonatal period with hypocalcemic seizures associated with hypoparathyroidism, velopalatal insufficiency, or cardiovascular malformations, rather than with recurrent infections. Infants with Wiskott-Aldrich syndrome (WAS)—immunodeficiency, thrombocytopenia, and eczema—present with petechiae and bruises similarly in the neonatal period. Obtaining a history of atopic disease is helpful. Atopic dermatitis has been associated with high risk of infection, including nondermatological infections.[10] For some patients with allergic rhinitis, management of allergies reduces the frequency of upper respiratory tract infection. In addition, it is important to inquire for a history of recurrent wheezing. At times, an initial history of recurrent pneumonia is, in fact, secondary to reactive airways disease or asthma. Other significant conditions include renal disease causing proteinuria or enteropathies that result in protein losses and secondary hypogammaglobulinemia.

Use of Medications

Use of particular drugs might also cause immunodeficiency, which could be *predictable,* such as the use of rituximab (anti-CD20 antibody) resulting in B-cell depletion and potential antibody deficiency, or *idiopathic,* such as hypogammaglobulinemia that might develop with the use of anticonvulsants.[11]

Family and Social Histories

Family history is essential in the evaluation of suspected immunodeficiency. A history of early infant deaths and possible consanguinity should be sought. A clear pattern of inheritance may be found to define an X-linked, autosomal dominant, or autosomal recessive genetic syndrome. Many of the most common PIDs have X-linked inheritance patterns. Family members of patients with immunodeficiencies might also have a history of autoimmune disease or of connective tissue disease. Familial cases of selective IgA deficiency and common variable immunodeficiency (CVID) have been reported, and a susceptibility trait can sometimes be traced back to many generations. A social history should be obtained for risk factors associated with increased risk of acquiring HIV infection. Socioeconomic factors often determine malnutrition, known to be of a significant impact on immune function.[12]

KEY CONCEPTS

Genetic Immunodeficiencies

- Diagnosis of genetic immunodeficiencies require high clinical suspicion and confirmation with molecular studies.
- In a minority of cases, genetic immunodeficiencies might not present with all clinical elements of classic descriptions. For example, patients with Bruton agammaglobulinemia might have residual B-cell and immunoglobulin production.

PHYSICAL EXAMINATION FINDINGS

The physical examination might provide findings that indirectly address the immune system; for example, scarred bilateral tympani suggest recurrent ear infections. More commonly, patients with immunodeficiency might otherwise look like normal individuals, unless severe infections had produced an organ damage or had delayed growth and development. However, attention to details in the physical examination may supply important clues that suggest immune dysfunction. In a normal child, a paucity of lymphoid tissue, such as tonsils and lymph nodes, might reflect impaired development resulting from immune deficiency. This is especially seen in patients with X-linked agammaglobulinemia. Certain physical findings are suggestive of syndromic immunodeficiencies, such as with telangiectasia over the bulbar conjunctivae and face with or without ataxia in ataxia–telangiectasia (AT); chronic eczema and delayed shedding of primary teeth in hyper-IgE syndrome (HIES); severe eczema in immunodeficiency, polyendocrinopathy and enteropathy, X-linked (IPEX) syndrome, and WAS; chronic periodontitis in defects of the neutrophils; or silvery hair, pale skin, and photophobia in Chediak-Higashi syndrome. Investigation for Shwachman-Bodian-Diamond syndrome (SBDS) should be considered in patients with neutropenia, especially if they also present with skeletal dysplasia. Patients with DiGeorge syndrome and nuclear factor-κB (NF-κB) essential modulator (NEMO) deficiency present with characteristic facies.

Children with severe immune defects are small for their age, with growth delay secondary to recurrent infections. Hepatosplenomegaly and diffuse lymphadenopathy might suggest HIV infection or a disorder of immune dysregulation. Children with leukocyte adhesion defect (LAD) can present with severe gingivostomatitis and dental erosion as a consequence of abnormal leukocyte function (Fig. 32.3). Multiple scars from skin abscesses might suggest neutrophil defects, and scarred tympani with reduced hearing might indicate a history of recurrent otitis media, which can be associated with antibody deficiency.

LABORATORY TESTING FOR IMMUNE FUNCTION

Results from commonly ordered tests might provide with a great deal of information about the immune system. The complete blood count (CBC) with differential and platelet determination is ordered to quantitate the total white blood cell (WBC) count and total numbers of neutrophils, lymphocytes, eosinophils, and platelets. Abnormal counts should be determined by using age-specific ranges. Leukocytosis, neutropenia, lymphopenia, and abnormalities in WBC morphology can be detected from this test. Persistent neutrophilia might suggest LAD. Anemia may be present in children with chronic disease. Platelet counts may be abnormally low in children with poor bone marrow function or autoimmune disease, and platelets will be reduced in number and morphologically small in children with WAS. Chemistry panels, including serum liver enzymes levels, might suggest organ compromise as a result of infections or autoimmunity associated with immunodeficiency. Low protein levels suggest malnutrition and conditions associated with protein losses, which may cause hypogammaglobulinemia. Examination of the posteroanterior and lateral chest radiographs to look for a thymic shadow can be helpful because its absence suggests impaired T-cell development. This is especially useful in infants because the thymus mass normally involutes with age. In addition, the thymus may shrink in response to such stresses as surgery, infection, or high-dose steroid treatment.

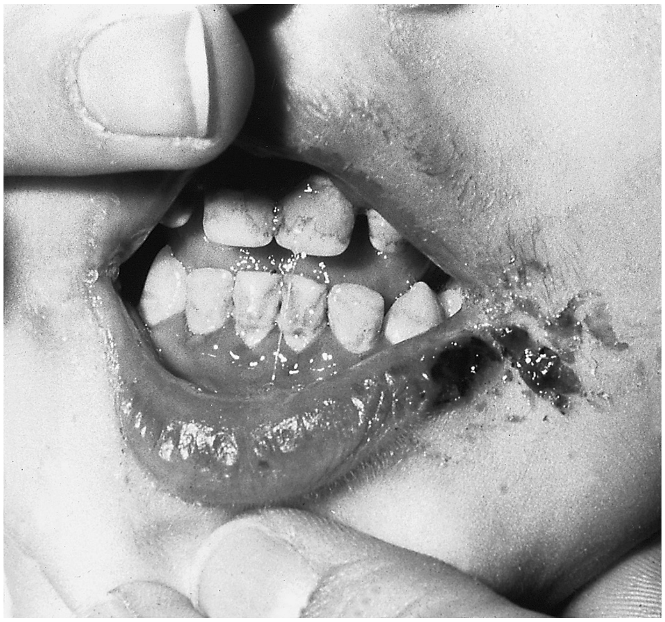

FIG 32.3 Severe gingivostomatitis and dental erosion in a 2-year-old child with leukocyte adhesion defect (LAD). (Courtesy of Dr. D.C. Anderson.)

HIV infection can be ruled out by screening with measurement of anti-HIV antibodies, by the enzyme-linked immunosorbent assay (ELISA) or the rapid HIV test. In those individuals with suspected humoral immunity defect and in children younger than 18 months of age, a polymerase chain reaction (PCR)–based test to detect HIV viremia should be performed to avoid false-negative results and confounding maternal anti-HIV antibodies, respectively.

Immunology Testing

Specific immunological testing is guided by clues obtained from the history and physical examination and common screening laboratory tests.

Serum Immunoglobulin Levels

The levels of IgG, IgA, IgE, and IgM can be measured in serum. The IgA level is especially helpful in that it is low in all permanent types of agammaglobulinemia and in selective IgA deficiency.

KEY CONCEPTS

Diagnosis of Immune Deficiencies

Features of Congenital Antibody Deficiencies

- Free of infections until 6–9 months of age, when maternal antibodies that passed through the placenta to infant are below protective levels
- Severe infections with bacterial organisms, especially sinusitis, otitis media, and pneumonias caused by encapsulated bacteria, such as *Streptococcus pneumoniae*

Features of Congenital T-Cell Immunodeficiency

- Onset of thrush, diarrhea, and failure to thrive in the first months of life
- Severe infections with opportunistic microorganisms, such as *Pneumocystis jiroveci, Candida albicans,* adenovirus, cytomegalovirus (CMV), Epstein-Barr virus (EBV). "BCG-itis" in areas where Bacille Calmette-Guérin (BCG) immunization is mandatory
- Absolute and relative lymphopenia

Screening Tests for Suspected Immunodeficiency

- Evaluation for neutropenia, lymphopenia, thrombocytopenia, and/or small platelets
- Immunoglobulin levels and specific antibodies to childhood immunizations
- Lateral chest radiography in infants for thymus shadow
- Consider flow cytometry to quantify T cells, T-cell subsets, B cells, and natural killer (NK) cells (especially in infants)
- Measurement of CH50 activity
- Test for oxidative burst in phagocytes

IgE level measurement is of significance for the diagnosis of HIES. Serum IgG subclasses levels can be determined. However, rather than using IgG subclass levels to screen for immunodeficiency, they are best utilized when patients have clinical conditions associated with specific antibody deficiencies but normal total IgG levels. In some of these patients, IgG subclass deficiency, particularly IgG2 and IgG3 deficiencies, might be present. IgG2 subclass deficiency has been linked with selective IgA deficiency and deficiency of antipolysaccharide antibodies. IgA subclass low levels, IgA1, IgA2, have not been associated with a specific immune defect, and there is no validity for measuring these. The variation of normal ranges of human serum Igs with age is an important consideration in children, since IgA and IgG subclass levels may not reach normal adult reference ranges until 6 years of age.[1]

B-Cell Function: Specific Antibody Production

To properly assess B-cell function, specific antibody production must be measured. Patients with normal Ig and Ig subclass levels might exhibit deficient antigen-dependent antibody responses. An initial screen of antibody production may involve the quantification of isohemagglutinins. Isohemagglutinins occur in all individuals except those with blood type AB; isohemagglutinins are natural IgM antibodies to polysaccharide blood group antigens A and/or B, which are not expressed in the red blood cells (RBCs) of the patient tested. Individuals form isohemagglutinins as a result of environmental exposure to ubiquitous antigens that share epitopes with blood antigens. Children less than 1 year of age do not reliably have measurable serum isohemagglutinins because of the limited exposure to the environment. A patient with blood type A should have anti-B IgM; patients with blood type B should have anti-A IgM; and patients with blood type O should have both anti-A and anti-B IgM. These antibodies are normally present in titers greater than 1:10; individuals with poor antibody production may have low or absent titers. Specific IgG antibody production can be measured following immunization with protein antigens, such as toxoids derived from *Tetanus* and *Diphtheria* organisms, and polysaccharide antigens, such as those produced by pneumococci and *Haemophilus influenzae.* For pneumococcal immunization, there are two vaccines that need to be differentiated. The conjugated vaccine containing 13 pneumococcal serotypes (PREVNAR13, Wyeth) is currently included in the universal schedule of immunizations for infants and toddlers and induces a robust, T cell–dependent immune response. The unconjugated 23-valent pneumococcal polysaccharide vaccine (Pneumovax, Merck) is available for immunization to adults and children aged 2 years and older. The immune response for this vaccine is considered less dependent on T cells and also less lasting than the conjugated vaccine. The pneumococcal antigen challenge using the unconjugated vaccine is not recommended for children under 2 years of age because healthy children are not thought to reliably respond to the unconjugated pneumococcal antigen at this age. However, this view has been challenged by data showing that 1-year-old children produce normal antibody responses to this unconjugated vaccine.[13,14] Normal antibody responses are usually demonstrated with an over twofold rise in specific antibody levels within 2–3 weeks for protein antigens and within 4–6 weeks for polysaccharide antigens.[15] Patients with agammaglobulinemia are expected not to produce antibody responses, whereas others, such as those with IgG2 subclass deficiency and normal levels of total IgG, may only have difficulty with antibody production following immunization with polysaccharide antigens. Patients with selective IgA deficiency, alone or with transient hypogammaglobulinemia of infancy, have normal specific IgG antibody production, by definition. The pneumococcal serotypes included in the current conjugated antipneumococcal vaccine, serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F, were estimated to be responsible for approximately 90% of invasive pneumococcal disease in children less than 5 years of age worldwide.[16] Previous immunization with the conjugate vaccine does not preclude use of the unconjugated pneumococcal polysaccharide vaccine. The 23-valent polysaccharide vaccine provides the potential for stimulation and measurement of a protective immune response to additional 11 serotypes (2, 8, 9N, 10A, 11A, 12F, 15B, 17F, 20, 22F, 33F) not included in the conjugated vaccine. Testing for antibodies against serotypes not included in the two vaccines and comparing the antibody titers in the pre- and postimmunization blood samples helps in the assessment of specific increase of particular antiserotype antibody titers as a response to the vaccine administration.

Evaluation of Cellular Immunity

Cellular immune function had been historically screened with the use of the delayed-type hypersensitivity (DTH) skin tests. DTH reactions occur 48–72 hours after antigen exposure, although antigens used to test DTH can occasionally produce immediate hypersensitivity reactions. The clinical response and time of observation were to discriminate between immediate and delayed reactions. DTH reactions involve the production of local edema and vasodilation as a result of inflammatory cytokines secreted by antigen-specific T cells, followed by lymphocyte infiltration and maximal induration 48 hours after antigen intradermal injection of an antigen. Generally, DTH skin tests are performed using vaccine antigens or microbial agents to which the patient

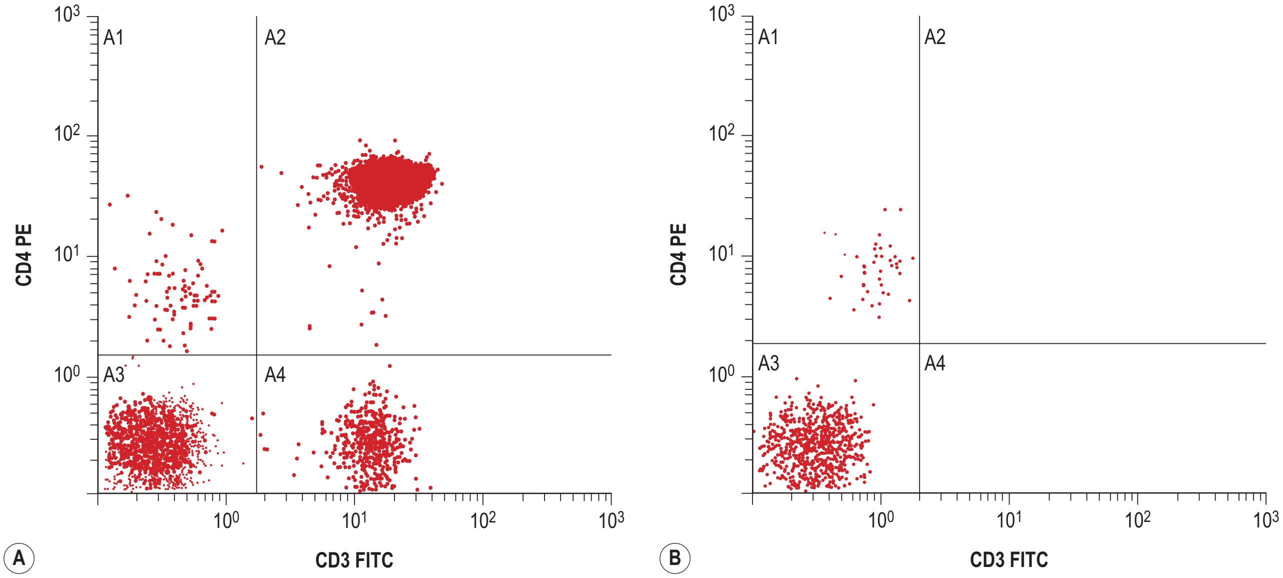

FIG 32.4 Histograms of Fluorescently Stained Lymphocytes. The quadrant of interest, A2, shows lymphocytes that are positive for labeling with both fluorescein isothiocyanate (FITC)–tagged monoclonal antibodies specific for CD3 and phycoerythrin (PE)–tagged monoclonal antibodies (mAbs) specific for CD4. The histogram on the left shows normal fluorescence as a result of CD4 T lymphocytes present in quadrant A2. The histogram on the right shows absence of CD4 T lymphocytes in an infant with SCID.

has had previous exposure. Commonly used antigens include tetanus toxoid, mumps, and extracts from *Candida albicans* and *Trichophyton* spp. The purified protein derivative (PPD), or tuberculin, can serve as a negative control in most patients in developed countries with a low incidence of tuberculosis. Likewise, a positive PPD result indicates sensitivity to mycobacteria as well as robust cellular immunity. Virtually all children and adults with previous exposure should respond to at least one antigen in a panel of tetanus toxoid, mumps, and *C. albicans*. *Anergy*, or nonresponse to the antigen following previous exposure, may indicate a cellular defect. A nonresponder should be retested with an *in vitro* lymphocyte evaluation.

Lymphocyte subset enumeration. Quantitation of B- and T-cell subsets narrows the differential diagnosis and provides evidence for the diagnosis of combined, cellular, or antibody immunodeficiency (Chapters 34, 35, 93, 94, 95,-96). Both T and B cells can be identified and labeled by using flow cytometry and fluorescent monoclonal antibodies (mAbs) (Chapter 92). T-cell enumeration involves the use of a pan–T cell mAb specific for CD3. The CD4 marker serves as identification for T-helper (Th) cells. CD8 marker characterizes cytotoxic T cells. B cells can be identified by using mAbs against the cell surface markers CD19 or CD20. Natural killer (NK) cells can be identified by using mAbs against CD16 and CD56. Specialized clinical laboratories are available to measure lymphocyte markers of importance to particular diseases; for instance, the proportion of αβ T-cell receptor (αβTCR) and γδTCR double-negative $CD3^+$ T cells are of relevance in the diagnosis of autoimmune lymphoproliferative syndrome (ALPS). T cell subsets can be characterized as naïve or activated based on the expression of CD45RA and CD45RO antigens.

B-cell panels and NK-cell panels. These panels have been designed to characterize the maturation stage of these cells and provide support for the diagnosis of an specific immunodeficiency. For example, the proportion of class-switched B cells has a predictive value for autoimmune and granulomatous complications in CVID.

In flow cytometry, the fluorescence intensity corresponding to cells labeled with each specific antibody is obtained (Fig. 32.4) and the percentage of the specific lymphocyte subset can be estimated. A reference range is available for each subset defining normal values as those whose values fall between the fifth and 95th percentages for this population. Separate ranges should be used for children because infants and children generally have higher absolute numbers of T-cell subsets and higher percentages of CD4 T cells (Fig. 32.5 and Appendix 2). Nonimmune factors, such as age, gender, and adrenocorticoid levels, influence the expression of blood lymphocyte subset populations. Therefore interpretation of lymphocyte phenotyping should take into consideration the clinical status of the patient. For example, transient moderate lymphopenia with predominance of T cells and NK cells might be seen in patients admitted to intensive care units. HIV infection causes progressive depletion of CD4 T cells. These abnormalities resolve when the patient's condition improves.

Lymphocyte functional analysis. To test lymphocyte function in the laboratory, mitogen- and antigen- induced lymphocyte proliferation or transformation studies are performed (Chapter 93). For these studies, lymphocytes are stimulated to proliferate involving new DNA synthesis and cell division. Lymphocytes from immunized or previously exposed individuals will normally proliferate in response to antigens to which they are sensitized. This response *in vitro* correlates with the *in vivo* DTH response. Mitogens, such as concanavalin A (ConA), phytohemagglutinin (PHA), and pokeweed mitogen (PWM), stimulate proliferation of normal T cells, as can allogeneic histocompatibility antigens when leukocytes from two donors are mixed in culture. Proliferation

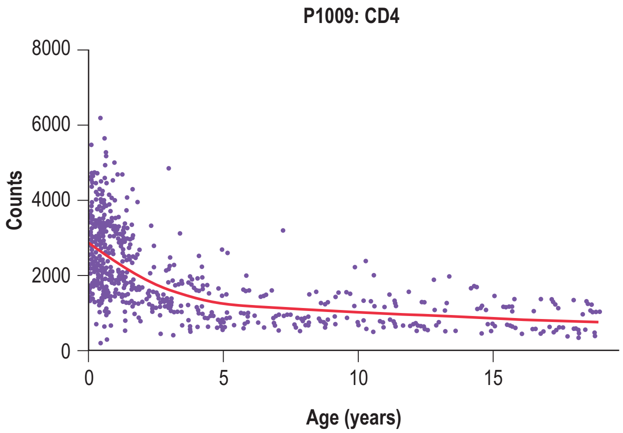

FIG 32.5 **Change in Distribution of Peripheral Blood CD4 T-Cell Subsets With Age in Healthy Children.** Scatter plot indicates peripheral blood CD4 T-cell counts (cells/μL) by age, with lowest curves in healthy children from birth to 18 years of age. (From Shearer WT, et al. Lymphocyte subsets in healthy children from birth through 18 years of age: The Pediatric AIDS Clinical Trials Group P1009 study. J Allergy Clin Immunol 2003; 112: 973, with permission from Elsevier.)

of lymphocytes can be evaluated by the demonstration of cell division or by increased DNA synthesis reflecting this cell process. Increased DNA synthesis is monitored by the incorporation of radiolabeled nucleotides, usually tritiated thymidine, in culture media. A measure of the amount of radioactivity in the cells correlates with DNA synthesis. Other assays to assess mitogen-induced cell proliferation measure deoxybromouridine incorporation, change in pH, or adenosine triphosphate (ATP) concentration of the culture media. These assays are being increasingly used as surrogate markers of cellular immunity; however, a comparison with the traditional assay based on radiolabeled nucleotide is not available. Of note, a flow cytometry assay that measures cell division with the use of carboxyl fluorescein succinyl ester (CFSE), a fluorescent compound that distributes evenly in cells and specific antibodies, is also increasingly used in clinical immunology.[17] CFSE is distributed equally in dividing cells, and each progeny cell has half the fluorescence intensity of CFSE compared with the parent cell, providing the basis to identify these dividing cells. After mitogen or antigen stimulation, mononuclear cells can be stained with specifically labeled antibodies, allowing the identification of cell subsets that proliferate.

Phagocytes

The laboratory evaluation of a patient with a suspected phagocyte deficiency (Chapters 22, 94) should always begin with a CBC. Neutropenia is the most frequently encountered disorder of the phagocyte system.[18] Neutrophilia, at values exceeding those associated with acute infection, is a common finding in LAD type 1 (LAD-1). Abnormalities of WBC function involve difficulty with adherence, locomotion, deformability, recognition, attachment, engulfment, phagosome formation, phagocytosis, degranulation, microbial killing, and elimination of engulfed material. Clinical assays to evaluate neutrophil function are limited in number. CGD is diagnosed by demonstrating absent or markedly reduced oxidase activity in neutrophils in response to stimulation. Oxidase activity can be detected by a flow cytometry assay measuring the oxidation of dihydrorhodamine (DHR) 123 in phagocytes, resulting in fluorescent rhodamine-123.[19] The nitroblue tetrazolium (NBT) test measures oxidative burst activity as well, but it is a more subjective test and can miss the diagnosis of CGD. For patients with suspected LAD-1 deficiency, neutrophils are labeled with mAb directed against the adhesion molecule CD11/CD18 heterodimer. Absence of fluorescence intensity indicates lack of expression of the adhesion molecule. In addition, an increase of fluorescence intensity after stimulation can be documented in normal individuals, indicating the normal upregulation of this molecule after cell activation.[20] Other laboratory techniques used to identify phagocytic defects include assays for chemotaxis and bactericidal activity. A major pitfall for neutrophil studies is the spontaneous cell activation that might occur *in vitro* when cells are not tested within a few hours of when the sample was drawn, resulting in artifactual values that might falsely suggest poor function.

Complement

Laboratory tests for complement components include tests for functional activity of the classical pathway with a CH50 assay and the alternative pathway with an AH50 assay, as well as immunochemical methods to measure complement component levels.[21] The CH50 evaluation tests the ability of fresh serum from the patient to lyse antibody-coated sheep erythrocytes. This reflects the activity of all numbered components of the classical complement pathway, C1–C9, and terminal components of the alternative complement pathway. A total deficiency of one of the classical complement pathway components will result in a CH50 assay approaching zero (Chapter 21). Patients with complement deficiency are rare, and complement test abnormalities are often transient because of increased consumption or activation. It is usually recommended that that in case of an abnormal result, the complement test be repeated if the sample was taken when the patient had an acute illness. Quantitative tests for components C3 and C4 are utilized in testing for complement deficiencies and for evaluation of complement activation (Chapter 21).

Innate Immunity: Interferon-γ Levels, Toll-Like Receptor Assay

The importance of the many components of innate immunity are increasingly recognized, as single gene defects in this immune compartment have been found to cause susceptibility to specific infections.[22] For example, patients with defects in the proteins that are part of the interferon-γ (IFN-γ) receptor may have elevated serum IFN-γ levels, even when there is no infection to explain these levels. The IFN-induced response associated kinase 4 (IRAK4) defect, observed with susceptibility to pneumococcal infection, might be accompanied with abnormal Toll-like receptor (TLR) assay responses. It should be noted that the clinical value of most of these innate immunity tests as screening or diagnostic tools for immune defects has not been clearly established.

The testing of lymphocyte apoptosis in a patient who may have ALPS and the evaluation of NK-cell function for suspected familial hemophagocytic lymphohistiocytosis are examples of specific functional assays that suggest immunodeficiency syndromes. Many patients with increased frequency of infections may not have abnormal results in clinically available immunological testing, which may not give clear evidence of a secondary etiology in the medical evaluation. In these difficult cases, referral to tertiary care and research centers for investigation of rare diseases is recommended.

MOLECULAR TESTING FOR PRIMARY IMMUNE DEFECTS

Molecular testing for specific PIDs is available through commercial and research laboratories.[23] Biochemical and genetic testing should be considered. If autosomal recessive SCID is suspected, the adenosine deaminase (ADA) and purine nucleoside phosphorylase (PNP) enzyme activities in the RBCs should be determined. White blood cells must be used to measure the activity of these enzymes in recently transfused individuals, since donor RBCs will elevate the enzyme activity in deficient patients. AT has the consistent laboratory finding of elevated alpha-fetoprotein (AFP) levels along with variable abnormalities in B- and T-cell function. Nearly 300 defective genes and gene products have been identified to result in congenital immunodeficiency syndromes.[24] In these cases, the diagnosis can be confirmed with molecular genetic analysis (Chapter 33). For example, gene mutations in *BTK* leading to the absence of Bruton tyrosine kinase (BTK) results in arrest of B-cell development at the pre–B cell stage in congenital X-linked agammaglobulinemia. Similarly, abnormal T-cell development leading to SCID results from mutations in at least 15 genes, including *IL2RG* and *JAK3*. Patients with gene mutations that may result in disease but have not been investigated need to be carefully evaluated to demonstrate the pathogenic nature of the genetic change. Some genetic changes do not have clinical significance and are known as single nucleotide polymorphisms (SNPs). Standard protocols using Southern, Northern, and Western blot analyses, PCR analysis, and DNA sequence analysis are helpful to identify affected patients, affected fetuses prenatally, and carriers of genetic mutations (Chapter 96). Most recently, the use of whole exome sequencing for immunodeficiency syndromes has facilitated the identification of new genes causing immunodeficiencies by examining all known gene exons without bias, and simultaneously. This methodology for diagnosis is particularly helpful when the clinical presentation does not match any of the already described immunodeficiency syndromes.[25]

CONCLUSIONS

CLINICAL PEARLS

Management of Immunodeficiency Patients

- Lymphopenia is a hallmark of T-cell immunodeficiency in infancy. Unexplained lymphopenia should be recognized and evaluated.
- Normal range for immunoglobulin levels and lymphocyte counts varies with age; age-matched controls should be used for interpretation.
- Survival and morbidity outcomes of hematopoietic stem cell transplantation (HSCT) for severe combined immunodeficiency (SCID) are best when performed in the first 4 months of age.
- Delays in treatment of immunodeficiency leads to infections causing permanent damage to organ systems, such as the lungs, where bronchiectasis or bronchiolitis obliterans may develop secondary to recurrent pneumonias.
- Implementation of universal screening of newborn infants by DNA analysis of dried blood spots on Guthrie cards (T-cell receptor excision circle [TREC]) detect all T-cell deficiencies.

The approach to the patient with suspected immune deficiency requires knowledge of developmental pathways and function of the different compartments of the immune system, as well as the clinical presentation of these disorders. The medical history, particularly the frequency, severity, and etiology of infections, is most helpful to orient the diagnostic workup. Commonly ordered tests in primary care, such as a CBC and serum Ig levels, are helpful to support possible diagnosis and referral to the clinical immunologist. Immunological testing according to clues obtained from the medical history helps narrow the differential diagnoses to specific immunodeficiencies, which are confirmed by molecular methods. Description of new T-cell subsets (*e.g.,* Th17 and regulatory T cells [Tregs]) has helped explain the immunopathogenesis of certain clinical manifestations, such as the occurrence of autoimmunity in patients with combined immunodeficiency, and "cold abscesses" in the autosomal dominant HIES. Testing for these lymphocyte phenotypes is being integrated in the clinical evaluation. Identification of genetic defects can now be accomplished by increased availability of whole exome sequencing, as an alternative to genetic analysis of candidate genes. Technological advances are making molecular diagnosis available for most patients with immunodeficiency conditions.

ON THE HORIZON

- Early diagnosis of severe combined immunodeficiency (SCID) and non-SCID is the key to successful hematopoietic stem cell transplantation (HSCT).
- Development of DNA sequence analysis for >300 types of primary immunodeficiency (PID).
- Wide availability of whole-genome sequencing methods to determine molecular defects for difficult to diagnose immunodeficiency syndromes

ILLUSTRATIVE CASES

Case 1

A 6-month-old Caucasian female infant was brought with a history of rash and otitis media that had been recurrent since 2 weeks of age. The infant had poor weight gain, frequent spitting up, coughing spells, and persistent diarrhea. Maternal HIV testing showed negative results. Physical examination revealed an emaciated infant without palpable lymphoid tissue and severe oral thrush. Cystic fibrosis was ruled out by using genetic studies. Stool viral cultures were persistently positive for rotavirus.

Immunodeficiency was suspected because of the infant's failure to thrive, persistent chronic diarrhea, and recurrent infection. An evaluation of the immune system was performed (Table 32.3). Humoral immunity testing showed Ig levels below or just above the lower limit of normal. Isohemagglutinins were not tested as the patient was less than 1 year old. As she had not been immunized, specific antibody titers to vaccines were not tested. Stool α_1-antitrypsin levels were normal, suggesting that protein was not being lost in stool, and urinalysis did not show protein loss. CBC revealed profound lymphopenia and absolute neutropenia. The neutropenia had resolved upon subsequent evaluations, but the lymphopenia persisted. A thymic shadow was not present on the chest radiograph. Evaluation of lymphocyte subsets by flow cytometry revealed that the CD4 and CD8 T-cell and B-cell numbers were all markedly low. The patient's lymphocytes had no proliferative response when stimulated with phytohemagglutinin. The history and the physical examination, along with laboratory values, including low Ig levels and markedly low lymphocyte numbers with poor proliferative response to mitogen stimulation, strongly suggested the diagnosis of SCID.

TABLE 32.3 Results of Screening Tests and Special Evaluations of Illustrative Cases*

	CASE NUMBER			
Test	**1**	**2**	**3**	**4**
Antibody Function				
Serum immunoglobulin (mg/dL)				
IgG	235 (208–686)	Normal	41 (256–1067)	748 (520–1340)
IgA	<8 (10–62)	Normal	7 (12–103)	40 (25–81)
IgM	<7 (43–183)	Normal	14 (47–173)	78 (64–275)
Isohemagglutinins	ND	ND	Negative	Normal
Functional antibody tests				
Antitetanus	ND	Normal	Undetectable	0.28
Antidiphtheria	ND	Normal	Undetectable	0.12
Anti-*Pneumococcus*	ND	2 of 14 protective	ND	Normal
Lymphocyte Numbers				
Lymphocyte count ($\times 10^3$ cell/μL)	0.217 (2.5–16.5)	2.8 (2.3–5.4)	2.56 (4.0–13.5)	10.60 (3.0–9.5)
CD4 number ($\times 10^3$ cell/μL)	0.009 (1.6–4.0)	1.27 (0.9–2.4)	1.72 (1.4–4.3)	ND
CD8 number ($\times 10^3$ cell/μL)	0.008 (0.5–1.7)	1.5 (0.5–1.5)	0.73 (0.5–1.7)	ND
CD19 number ($\times 10^3$ cell/μL)	0.010 (0.3–2.0)	0.023 (0.4–1.4)	0.107 (0.6–2.6)	ND
Lymphocyte Proliferation (counts/min)				
PHA, Phytohemagglutin	546 (55494)	Normal	210973 (177195)	ND
ConA, Concanavalin A	ND	Normal	124680 (143591)	ND
PWM, Pokeweed mitogen	ND	Normal	162646 (138684)	ND
Complement Function				
Total hemolytic complement (U/mL)	ND	ND	618 (300–500)	<100 (300–500)
Phagocyte Function				
Neutrophil count (x10e3 cell/mL)	0.109 (1.0–9.0)	0.570 (1.5–8.5)	3.3 (1.0–8.5)	4.2 (1.5–8.5)
Monocyte count (x10e3 cell/mL)	0.546	Normal	0.11	0.65
Oxidative activity (DHR)	ND	Normal	Normal	ND

*Normal values are reported in parentheses. Normal values may vary from laboratory to laboratory as a result of different techniques used and may vary according to patient age.
ConA, concanavalin A; DHR, dihydrorhodamine; ND, not done; PHA, phytohemagglutinin; PVVM, .

The patient had low levels of ADA and increased levels of the toxic nucleotide metabolites. SCID as a result of ADA deficiency was diagnosed.

Following ADA enzyme replacement therapy and Ig infusions, the patient thrived and had fewer infections. Her lymphocyte numbers and function improved.

Case 2

A 4-year-old female child was presented with a history of short stature and frequent upper and lower respiratory infections. Family history was not contributory. Physical examination was remarkable for height and weight less than the fifth percentile for age and a significant chest deformity (Fig. 32.6). Radiological examination demonstrated metaphyseal dysplasia and *pectum carinatum*, with significant bilateral lung atelectasis. Hematological evaluation showed severe neutropenia, a normal lymphocyte count, and mild thrombocytopenia (see Table 32.3). Examination of bone marrow revealed mild dysplasia with the presence of three lineages and no evidence of chronic viral infections. Evaluation for failure to thrive was significant for low levels of pancreatic enzymes. A sweat test was done to screen for cystic fibrosis, and the result was normal.

Immunological evaluation showed normal serum levels of IgG, IgA, and IgM, with mildly increased IgE levels. Specific antibody responses to childhood vaccines were protective against tetanus, diphtheria, and *H. influenzae* antigens, and to only two of 14 pneumococcal serotypes were measured despite the child being fully immunized. Lymphocyte phenotyping revealed low B cells and NK cells. A diagnosis of Schwachman-Bodian-Diamond syndrome (SBDS) was made on the basis of the patient's unique clinical manifestations. Genetic sequencing analysis of the *SBDS* gene identified one mutated allele that had not been previously reported, and molecular investigations for chromosomal breakage defects, other skeletal genetic syndromes, and mitochondrial defects showed negative results. The patient was treated with pancreatic enzyme replacement, antibiotic prophylaxis, and close hematological follow-up.

Case 3

A 12-year-old Caucasian male child had a history of diarrhea that lasted for 1 month, nuchal rigidity, left facial weakness, and a left sixth cranial nerve palsy when he was 8 months of age, although he had been well for the first 6 months of life. The family history was negative for immunodeficiency. The patient had received his childhood immunizations, including the live polio virus vaccine. Physical examination revealed absence of tonsillar tissue, and the patient had no palpable lymph nodes. The presenting neurological symptoms resolved, but the patient subsequently developed a lower-extremity flaccid paralysis that has persisted.

Immunodeficiency was suspected because of the chronicity of the illness, the lack of lymphoid tissue on physical examination, and the finding of an unusual infectious agent causing severe sequelae to infection. The age at presentation was typical for

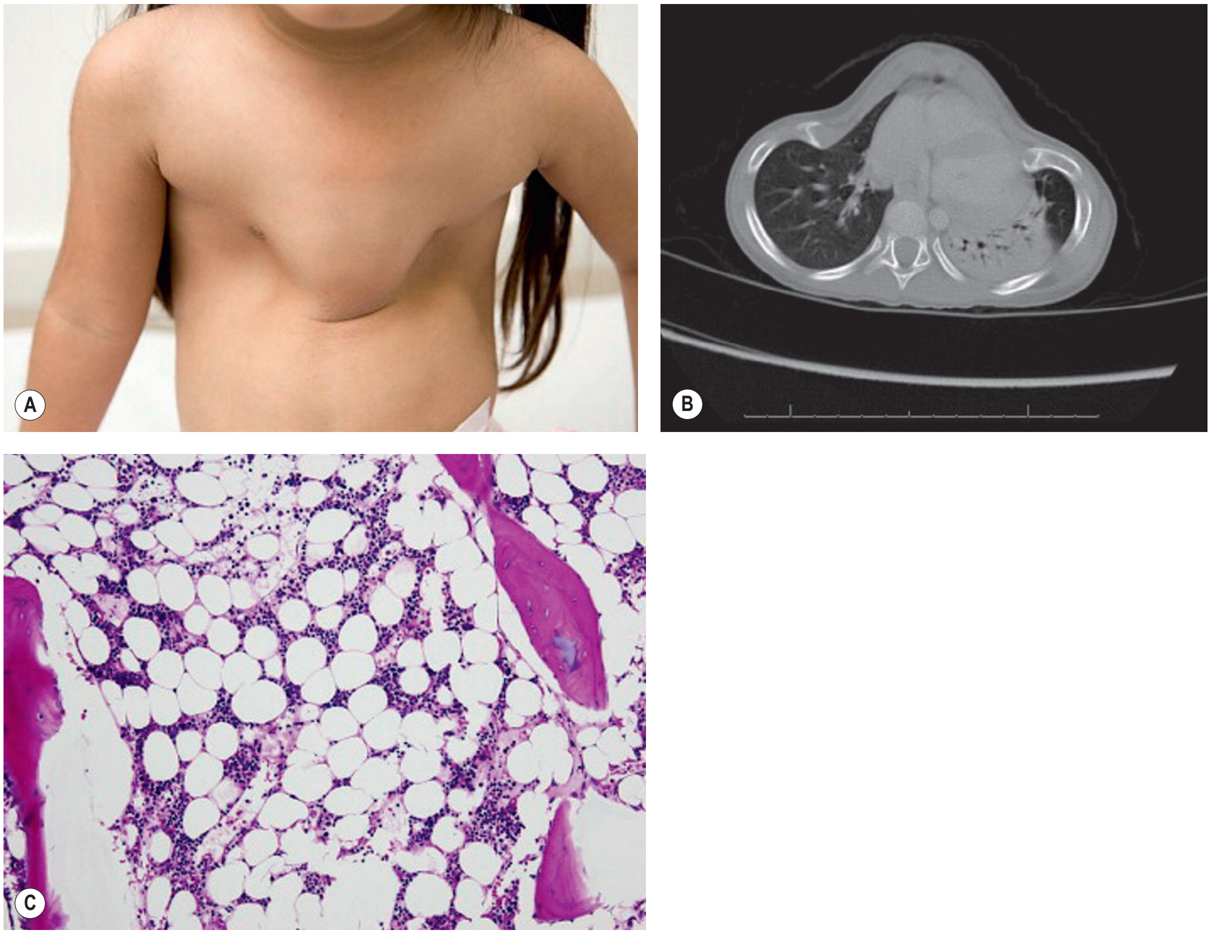

FIG 32.6 **A 4-Year-Old Girl Presenting With Congenital Neutropenia, Small Stature, and Pancreatic Insufficiency.** Genetic sequencing analysis confirmed diagnosis of Schwachman-Bodian-Diamond syndrome. (A) *Pectus carinatum.* (B) Chest computed tomography (CT) scan. (C) Bone marrow biopsy (hematoxylin and eosin stain; original magnification, ×100). (From Shah SS, et al. Diagnosis of primary immunodeficiency: let your eyes do the talking. J Allergy Clin Immunol 2009;124:1363–4, with the permission from Elsevier.)

patients with a defect in humoral immunity. Immune system evaluation (see Table 32.3) showed a normal absolute neutrophil count and a low absolute lymphocyte count. The CH50 was mildly elevated; this result ruled out a complement component deficiency from the differential diagnosis. Ig levels were low. Antibody levels to diphtheria and tetanus were very low. A thymus shadow was present on the chest radiograph. Lymphocyte evaluation showed normal numbers and percentages of T cells and absent numbers and percentages of B cells. Proliferative responses of lymphocytes to mitogens were normal. Molecular testing showed a mutation in the *BTK* gene. The CSF was remarkable for lymphocytic pleocytosis, but the protein and glucose levels were normal. Stool and throat cultures revealed vaccine-strain poliovirus. The patient was diagnosed with vaccine-acquired polio virus infection and X-linked agammaglobulinemia.

The patient receives monthly Ig replacement therapy and is otherwise well.

Case 4

The patient was a 3-year-old girl who was hospitalized for pneumonia. Her past medical history was significant for recurrent otitis media and bronchitis. The family history was negative for diagnosed immunodeficiency, although two siblings had a history of recurrent otitis media and bronchitis. The physical examination revealed normal tonsillar tissue and the presence of small lymph nodes in the cervical region.

Laboratory values (see Table 32.3) included normal numbers of granulocytes and lymphocytes. Serum Ig levels were normal. The patient had been immunized and had adequate antibody titers to tetanus, diphtheria, and *Pneumococcus* antigens. The CH50 level was below the lowest measurable level. C3 and C4 levels were normal, but the level of C2 was 0. The patient's father, mother, and brother had levels of C2 that were half the normal value, consistent with being heterozygous for an abnormal C2 allele. C2 deficiency was diagnosed. The patient has had chronic sinusitis and bronchitis despite antibiotic prophylaxis. C2 deficiency is most frequently associated with autoimmune disease; this patient has not had autoimmune disease and undergoes yearly surveillance examinations.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following diagnoses is most likely to present with *Pneumocystis jiroveci* pneumonia during the first year of life?
   A. Partial DiGeorge syndrome
   B. Human immunodeficiency virus (HIV) infection
   C. Common variable immunodeficiency (CVID)
   D. Chronic granulomatous disease (CGD)
   E. Complement deficiency

2. Deficiencies of terminal component of the complement system is associated with frequent or severe infections caused by:
   A. *Candida* spp.
   B. Epstein-Barr virus
   C. *Neisseria* spp.
   D. *Mycobacterium tuberculosis*
   E. *Cryptosporidium parvum*

3. Which of the following conditions is MOST likely to contribute to frequent respiratory infections?
   A. Adolescence
   B. Peanut allergy
   C. Dust mite allergy
   D. Homeschooling
   E. Protein-rich diet

Human Genomics in Immunology

Robert L. Nussbaum, Jennifer M. Puck

The completion of the Human Genome Project in 2003, 50 years after the landmark 1953 publication of the double-helical structure of DNA by James Watson and Francis Crick, is correctly deemed a major milestone in modern biology. The sequence provided a first comprehensive and accurate view of the genetic makeup of humans, with a low error rate and only a few hundred gaps of indeterminate sequence. The first detailed picture of the structure of a composite human genome is for human genetics what Vesalius's publication of a consensus structure of the human body, *De humani corporis fabrica,* was for anatomy. And, like Vesalius's work, it continues to serve as a foundation for further scientific discovery in such areas as genetic variation, gene function, human physiology, and the genetic basis for disease. The years following the completion of the first human genome sequencing have seen progress in all of these areas.

KEY CONCEPTS

The sequence of the human genome and catalogue of extensive genome variation among humans has revolutionized our approach to heritable immune disorders.

Genomic variation between humans and other species illuminates conserved areas that are critical for normal function of gene products.

A variety of types of DNA variation are recognized, including single nucleotide changes, insertions or deletions of a few to many nucleotides, copy number variants, and structural variants.

Interpretation of the significance of an observed variant in DNA sequence may require consideration of its location, frequency in the population, inheritance in a family, and specific effect on the resulting gene product.

GENOME ANNOTATION

A consensus sequence of the human genome is only the first step in furthering our understanding of normal biological functions and how mutations lead to abnormal functions that cause disease. The Human Genome Project has now matured into a number of important basic and applied research areas: *(i)* acquiring a comprehensive catalogue of human variation and the impact of such variation on phenotype, including disorders of human development; *(ii)* comparing the genomes of humans with those of other organisms, including model organisms and human ancestors; and *(iii)* learning how to interpret all the sequence elements within the genome, not just the codons. Even now, over a dozen years after "completion" of the human genome sequence, a complete, accurate, and single contiguous stretch representing a reference human haploid genome is still being constructed, and updated versions of the genome sequence continue to be released. As described below, the greatest challenges to completing the human genome sequence are posed by regions that contain segmental duplications of nearly the same sequence.[1]

HUMAN VARIATION

The first publicly available human genome sequence was constructed from a small number of individuals. Nonetheless, the "reference" human genome sequence available at public websites is a consensus, composite haploid sequence and not the sequence of any one individual. It is neither a "normal" genome nor a "control" genome; instead, it serves as a reference, providing a universally available sequence against which the genomes of other individuals, as well as other species, can be compared and any differences ("variants") determined. Even before the original human genome sequence was completed, the need to discover as broad a range of human variations as possible in populations from around the world was clearly recognized to be essential if we were to begin to understand how variations in the genome lead to differences in phenotypic variations in traits and disease susceptibilities. The first concerted efforts to catalogue human genetic diversity after completion of the Human Genome Project was the dbSNP (database of single nucleotide polymorphisms) project, followed by the 1000 Genomes project. These initial catalogues that surveyed the extent of variation in both the coding and the noncoding portions of the genome have been supplemented enormously by more comprehensive sequencing efforts, which produced the NHLBI GO Exome Sequencing Project (ESP) and Exome Aggregation Consortium (EXaC). These projects focus on variation within exomes of hundreds of thousands of individuals and have made a vast number of variants and their frequency publicly available to researchers and clinicians worldwide.

Variants can be classified as rare or common (polymorphic) according to their *frequency* in a population under study. Any variant present in >2% of the population (*i.e.*, constituting >1% of the alleles at any locus in that population) is arbitrarily designated as polymorphic. With the advent of comprehensive DNA sequencing of larger and larger numbers of people from across the globe, it has become clear that most variants (85%) at any one base pair (bp) or segment of the genome have allele frequencies substantially below the 1% cutoff for being a polymorphism and are, instead, considered rare, sometimes restricted to a single ethnic group or even a single kindred.[2]

DNA variation can also be classified according to the *type* of DNA change seen in the variant (Table 33.1). Single nucleotide variants (SNVs), insertion/deletion variants (indels), copy number variants (CNVs), and structural variants (SVs) can have different

TABLE 33.1 **Types of DNA Variation**

Type	Description	Ability to Detect	Frequency in an Individual
Single nucleotide variants (SNVs)	A sequence change where, compared with a reference sequence, one nucleotide is substituted for another nucleotide	High	3–4 000 000
Deletion or duplication variants (Del/Dups)	A sequence change involving between 2 and ~1000 base pairs (bp) in which reference nucleotides are either not present (deleted) or are duplicated and inserted directly 3′ of the original copy of the sequence	Moderate	1 000 000?
Insertion/deletion variants (Indels)	A sequence change involving between 2 and ~1000 bp in which one or more reference nucleotides are replaced by one or more other nucleotides and is not an SNV or SV	Moderate	
Copy number variants (CNVs)	Del/Dup or Indel arbitrarily set as larger than ~1000 bp	Difficult	
Structural Variants (SVs)		Very difficult	

From Human Variome Society, Sequence Variant Nomenclature. 2016. Available at: http://varnomen.hgvs.org.

consequences, depending on their location and the number and identity of nucleotides affected.

The simplest and most common of all variants are SNVs, in which one nucleotide in the reference sequence is substituted by another. A locus characterized by an SNV usually has only two alleles, corresponding to the more common (major allele) and less common (minor allele) bases found at that particular location in the genome, although, theoretically, four alleles at any one base position are possible. SNVs are observed on average once every 1000 bp in the genome but are not distributed evenly throughout and are most often not equally frequent throughout all populations. Most SNVs are found in the 98% of genomic sequence that is not within exons, including the ~20% of the genome inside genes, in introns, with the remaining ~80% between genes. Nonetheless, many SNVs are in coding portions of genes and other known functional elements in the genome. Just under half of these do not alter the predicted amino acid sequence of the encoded protein and are thus termed *synonymous*, whereas the remainder do alter the amino acid sequence and are said to be *nonsynonymous*. Other SNVs introduce or change a stop codon, and yet others alter a known splice site; such SNVs are expected to have significant functional consequences.

A second general class of variation is the result of insertion and/or deletion of reference sequence ranging from 1 up to an arbitrary cutoff of ~300–1000 bp, that is, a variant size that can be detected by the most commonly used next-generation sequencing (NGS) technology. When reference nucleotides are simply deleted or duplicated, the variant is referred to as a "del/dup." When reference sequence has some nucleotides deleted and *replaced* by other inserted sequence, the variant is referred to as an "indel." Approximately half of all del/dups are referred to as "simple" because they have only two alleles—that is, the presence or absence of the inserted or deleted segment. Each individual is known to carry hundreds of thousands of indels, but this estimate is suspected to be too low, and a corrected estimate for indels per individual may be upward of a million.[3] Up to 30–40% of actual indels are likely to be missing from catalogues because of the technical difficulties of distinguishing many indels from sequencing errors using the current sequencing technologies.[4]

Some del/dup variants are multiallelic because of variable numbers of the identical segment of DNA inserted in tandem at a particular location, thereby constituting what is referred to as a *microsatellite* (also referred to as a *short tandem repeat* [STR]). Microsatellites are segments of DNA composed of units of 2, 3, or 4 nucleotides, such as TGTG …TG, CAACAA …CAA, or AAATAAAT … AAAT. The units are repeated between two and a few dozen times at a particular site in the genome. Some variation in microsatellite length is common enough to constitute a *polymorphism*, defined as an allele or alleles other than the reference sequence, found in ≥2% of the population. Many tens of thousands of polymorphic microsatellites are known to exist throughout the human genome. There are, however, STR DNA segments present within exons or splice junctions of >90% of genes associated with human disease. They rarely, but famously, can expand to become hundreds or thousands of nucleotides long, thereby causing such human disorders as fragile X syndrome or Huntington disease. Even without expansion, STRs within exons, some of which may be as small as 9–25 bp, have an outsized impact on the frequency of human disease, since they confer a five- to sixfold increase in the frequency of rare disease-causing indel mutations compared with neighboring exon sequences that do not contain an STR.[5]

One subclass of indel variants arises from mobile elements. Nearly half of the human genome sequence consists of families of repetitive elements dispersed throughout the genome, of which the two most common are the *Alu* (a short interspersed nuclear element [or SINE]-usually about 300 bp) and LINE (long interspersed nuclear element) families of repeats. Although most of the copies of these repeats are stationary, some of them contribute to human genetic diversity through *retrotransposition*, a process that involves insertion of a DNA segment generated through transcription of an *Alu* or LINE element into an RNA that is then reverse-transcribed into a DNA sequence that is inserted into the genomic DNA. Each mobile element indel consists of two alleles, one with and one without the inserted mobile element. Mobile element polymorphisms are found on all human chromosomes; although most are found in nongenic regions of the genome, a small proportion exist within genes. At least 5000 of them are known to be frequent enough to be polymorphisms, and insertion frequencies of >10% occur in various populations; other mobile elements are rare and have been implicated in causing insertional mutations in human disease genes. As with other indels, difficulties with sequencing, in particular the challenges posed to NGS by repetitive DNA, result in underestimation of *Alu* and LINE indels throughout the genome.[3]

Another important type of human variation includes CNVs. These consist of variations in the number of copies of segments of the genome that are larger than those involved in indels and range in size from 1000 bp to many hundreds of kilobase (kb) pairs. Variants larger than 500 kb are found in 5–10% of individuals in the general population, whereas variants encompassing more than a million bases (1 Mb) are found in 1–2%.[6] Smaller CNVs, in particular, may have only two alleles (*i.e.,* the presence or absence of a segment), similar to indels. Larger CNVs tend to have multiple alleles because of the presence of different numbers of copies of a segment of DNA in tandem. The content of any two human genomes can differ by as much as 50–100 Mb as a result of copy number differences at CNV loci, compared with some 3–4 Mb of differences because of SNVs and indels. Thus simply on the basis of the number of nucleotides involved in the variation, CNVs represent vastly more human variation than do SNVs or indels.

Not only are CNVs a very significant contributor to human variation and disease,[7] the areas of the genome where they are found are often the sites of segmental duplications,[8] some of the most difficult regions in which to develop an accurate reference sequence. Segmental duplications are ubiquitous throughout the genome. It is difficult to construct an accurate contiguous genome sequence in regions of segmental duplications because the most widely used massively parallel sequencing technologies generate only short reads of a few hundred base pairs and therefore may not be able to differentiate between the sequences of nearly identical DNA segments using unique DNA that flanks them. The assembly algorithms, which always try to create the simplest assembly possible, may consider two nearly identical segments of DNA that have been duplicated in the genome, but differ at a few locations in their sequence, to be the same sequence and collapse them into a single segment of DNA. The fixed sequence differences between the duplicated segments are incorrectly interpreted as polymorphic differences between two alleles of a nonduplicated locus instead of being real sequence differences between different copies of duplicated DNA. The fact that there is a segmental duplication is therefore overlooked. Conversely, the sequence of a unique DNA segment with many SNVs compared with the reference may be incorrectly interpreted as having come from distinct but highly similar duplicated segments, leading to the supposition that there are paralogues or duplicated segments. As a result, segmental duplications are liable to both false-negative and false-positive representations in the human genome assembly. CNVs are particularly difficult to detect and interpret if the number of segments in the reference is incorrect or ambiguous.

Many CNVs include genes, from one up to several dozens; thus CNVs are frequently implicated in diseases that result from altered gene dosage.[7] One well-known human immunological multisystem disorder, DiGeorge syndrome, is caused by a deletion CNV that occurs *de novo* in about 1 in 5000 individuals. When a CNV is more frequent, it represents a background of common polymorphism that must be understood if to properly interpret alterations in copy number observed in patients. As with all DNA variations, the significance of different CNV alleles in health and in disease susceptibility is the subject of intensive investigation.

The most common SVs in the human genome sequence are inversions, which differ in size from a few base pairs to large regions of the genome (up to several Mb) that can be present in either of two orientations in the genomes of different individuals.[8] As with CNVs, inversions are usually flanked by regions of sequence homology, which indicates that recombination of these homologous regions is likely involved in the origin of the inversions.[7,8] Most inversions do not involve gain or loss of DNA; in this case, the two alleles corresponding to the two orientations can achieve substantial frequencies in the general population. Such inversions can, however, cause significant gains or losses of DNA in the offspring of inversion carriers because of aberrant recombination during meiosis, leading to serious syndromes brought about by chromosomal imbalance. Furthermore, if inversions interfere with normal gene expression by disrupting a gene or altering the physical relationship between a gene and its regulatory elements, it may be detrimental to health.[9,10]

CLINICAL IMPACT OF HUMAN VARIATION

One of the greatest challenges facing human geneticists is linking variation to phenotype.[11] The significance for the health of the vast majority of variants of any type is unknown, and yet this knowledge is essential if we are to apply genomics to clinical care. The impact of variants ranges from completely benign to highly pathogenic, the latter causing devastating disorders of the immune system that may occur as new mutation dominants or as autosomal recessively inherited syndromes. Even common polymorphic variants may affect health or longevity, although their being common means that they are likely to produce a relatively subtle alteration of disease susceptibility rather than directly cause a serious illness.[12] Working out the functional impact of human variation will occupy genomics researchers for many years to come. An essential component of this work is to make databases of genetic variants and their impact on human health available to the research and clinical communities, as is being done with the ClinVar database hosted by the National Library of Medicine in the United States and the Leiden Open-source Variation Database (LOVD).[13-15]

COMPARATIVE GENOMICS

Evolution at work is nowhere better illustrated than in the field of comparative genomics, which deals with similarities in the sequence, structure, and chromosomal location of genes between different species whose evolutionary paths diverged from a few years ago to many hundreds of millions of years ago. Direct sequence comparison has revealed that an enormous number of human proteins have orthologues (genes derived from a common ancestor) in other organisms, ranging from 87% in chimps to 79% in mice, 63% in zebrafish, 39% in the fruit fly (*Drosophila melanogaster*), and 31% in the nematode (*Caenorhabditis elegans*) (Fig. 33.1). The study of the human genome and the genomic basis for human disease has benefited from studies done in other organisms, particularly mice, in which many decades of inbreeding and gene manipulation have permitted study of the genes and underlying mechanisms by which mutations responsible for immune defects lead to phenotypes. Mouse models of immunity have been highly relevant and informative for humans.

However, orthologous genes may serve different functions in different species; therefore one cannot assume that a disease-causing mutation in humans will cause a similar defect when its orthologue is similarly mutated in mice, and vice versa. For example, the V(D)J recombination activating genes *RAG1* and *RAG2* in humans and *Rag1* and *Rag2* in mice appear to have identical functions, with knockout mice showing the same inability to recombine T- and B-lymphocyte antigen receptor genes as humans with RAG1 or RAG2 deficient severe combined immunodeficiency (SCID; Ch. 35).[16] As a result, the lymphocyte profile in both species is absent T and B cells with normal natural killer (NK) cells, referred to as $T^-B^-NK^+$ SCID. A contrasting situation occurs in other SCID genotypes. For example, humans lacking the common γ chain (γc) of receptors for interleukin-2 (IL-2) and other cytokines, caused by mutations in the X-linked gene *IL2RG* have SCID in which T and NK cells are absent but nonfunctional B cells are present in normal to high numbers, $T^-B^+NK^-$ SCID. Mice with the orthologous gene *Il2rg* mutated or removed can make T cells but have no B cells, which gives them a $T^+B^-NK^-$ phenotype.[17]

Genes other than *IL2RG* alone must be responsible for this difference between species. Such genes, known as *modifiers,* have not yet been identified. Notably, different strains of mice can also have important phenotypic differences in the presence of a single gene mutation under study; some strains, for example, nonobese diabetic (NOD) and Murphy Roths Large (MRL) mice are highly prone to developing autoimmunity, while others such as C57BL/6 (B6) are resistant.[18]

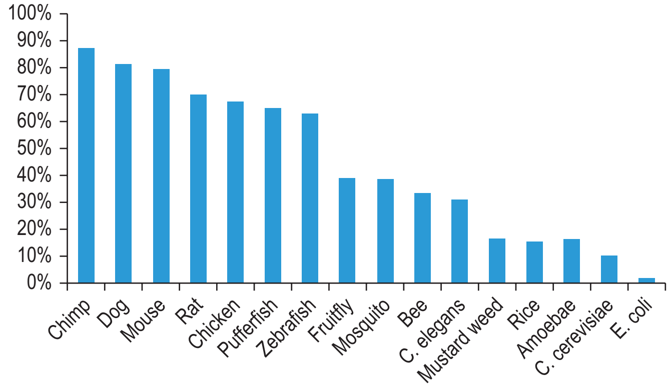

FIG 33.1 Homology Between Human Genes and Genes in Multiple Other Organisms. Comparisons were made by calculating gene homology or similarity between reference protein sequences from human and another species, with homology considered present when the probability of an interspecies match by chance alone was $<10^{-30}$. New York: Oxford University Press; 2008).

FUNCTIONAL GENOMICS

Immediately after the Human Genome Project was declared to have been completed in 2003, an important follow-on project was launched to identify the functional segments of DNA, particularly portions in the 98–99% lying outside of the coding exons of genes, for which there was no simple sequence code that could be understood the way the triplet codon code can be read. This project, termed ENCODE (for "encyclopedia of DNA elements"), began as a pilot project to identify functional elements in 1% of the genome, but it was quickly expanded to include the entire human genome as well as the genomes of model organisms.[19] Before ENCODE, estimates were that 3–8% of the human genome had some role in function, given that this fraction of the genome appeared to be highly conserved among species with only very limited variation. This estimate was clearly too low, as it did not take into account rapidly evolving functional elements or those restricted to particular evolutionary lineages. This estimate also did not include segments of DNA that were too small to show conservation with statistical significance, nor did it include the functional elements in repetitive DNA that are not reliably scored as being evolutionarily conserved.

Since the same genome is present but functions differently in different cells of an individual, ENCODE used a number of different tissues for its studies (Fig. 33.2). A comprehensive catalogue of every segment of DNA that is transcribed into RNA in any tissue, including all splice isoforms, was required, including RNAs that code for a protein or are noncoding and function in gene regulation. ENCODE is analyzing not only total whole-cell RNAs but also those located in the nucleus or cytosol because subcellular localization of RNAs is important in how RNA is processed and functions. Other assays for functionality of segments of DNA include biochemical evidence, such as identifying

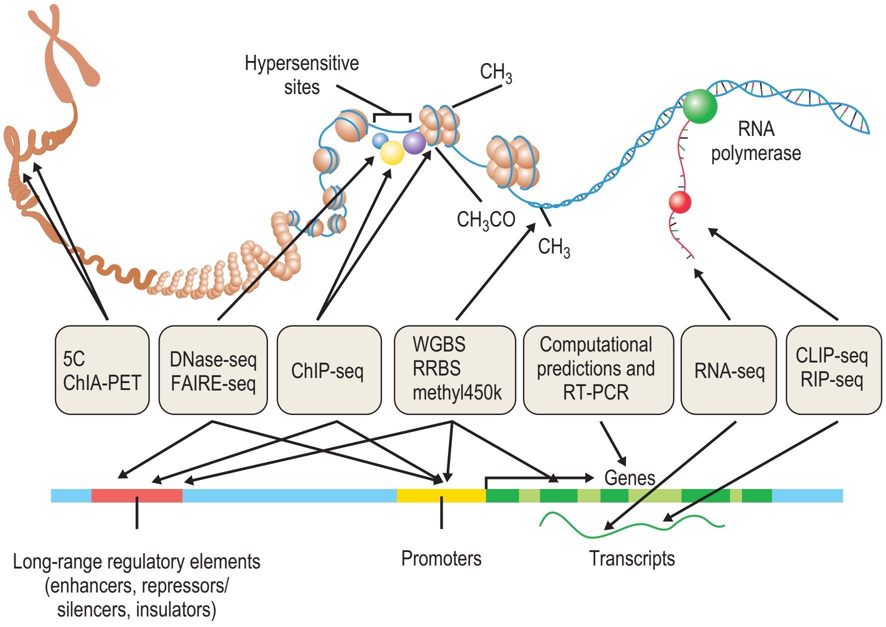

FIG 33.2 Diagram of Various Transcriptional and Chromatin Assays Being Used in the ENCODE Project. The assays can be used to identify regions of the genome involved in the regulation of gene expression. (With permission from https://www.encodeproject.org.)

(i) segments of DNA located in chromatin loops that allow chromatin–chromatin interaction; *(ii)* regions of open chromatin, which are accessible to transcription; *(iii)* motifs that bind transcription factors; *(iv)* regions that are associated with histones that have been modified to either promote or suppress transcription; and *(v)* regions with differential methylation of cytosine residues in different tissues, with methylation being associated with inactivity.

Now, approximately 15 years into the project, ENCODE has created a large database of more than 4 million functional regions of the genome. Mostly on the basis of biochemical evidence, it has been estimated that 80% of the genome *may* be of functional significance,[20] but this estimate is probably too high and has been strongly criticized. For example, evidence of transcription of a segment does not necessarily mean that the transcript plays any functional role, nor is it likely to be true that the millions of vestigial repetitive DNA sequences that are undergoing mutation without any apparent selection could have important functional roles.[21] A more stringent threshold for ascribing a functional role to DNA segments (*i.e.,* direct effect on gene expression and phenotype of at least one human cell type) reduces that fraction to the range of 10–20%. Much more research will be needed before the ENCODE project delivers its final assessment of the fraction of the human genome that plays a role in gene regulation—that is, in how different cells use their genomes.[22]

APPLYING HUMAN GENOMICS TO UNDERSTANDING DISORDERS OF THE HUMAN IMMUNE SYSTEM

Genome research has provided geneticists with a catalogue of all known human genes, knowledge of their location and structure, and an ever-growing list of variants in DNA sequences found among individuals in different populations. In the past, geneticists followed two approaches to identifying the genetic basis for human disorders. The first approach, linkage analysis, is *family based* (Fig. 33.3). Linkage analysis takes advantage of family pedigrees to follow the inheritance of a disease among family members and test a few hundred DNA variants distributed throughout the genome for consistent, repeated coinheritance, or segregation, with the disease. A demonstration of significant coinheritance with a *variant* or *variants* located in a particular region of the genome indicates that the disease-causing mutation is also located in a gene within or near this region. The variants showing coinheritance with the disease are usually not the variants responsible for the disorder. Marker variants need, however, to be located close enough that recombination between the marker and the gene mutation responsible for the disease is sufficiently rare that cosegregation is observed over a few generations.

The second approach, genome-wide association analysis (GWAS), is *population based.* A sample of affected individuals, or "cases," taken from the population, is chosen along with a matched set of unaffected "control" individuals from the same population. Then, a large number, in the order of a million or more, variants are examined individually for an increased or decreased frequency of cases compared with controls. The alleles used to *test* for association need not be the actual variants functionally *responsible* for the disease association—in fact, it is highly unlikely this would be the case. Instead, GWAS, like linkage, depends on the vast number of marker alleles that can be tested for association to be located close enough to the alleles functionally responsible for association to have been carried along, on the same chromosome in a haplotype block, through many generations (Fig. 33.4). Association analysis does not require pedigrees and is particularly useful for complex diseases that do not show strict mendelian inheritance.

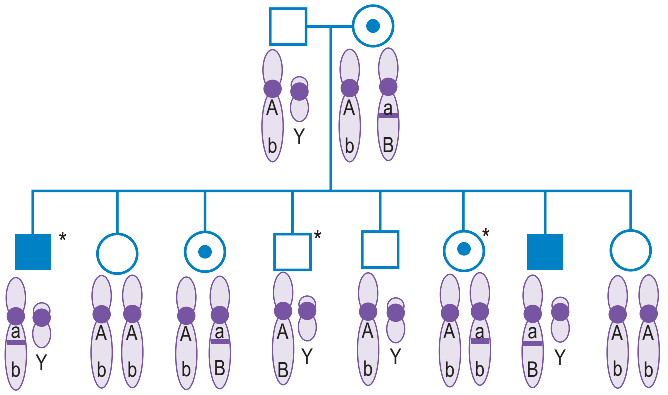

FIG 33.3 An Example of Family-Based Linkage Analysis as a Means to Identify a Disease Gene. The pedigree of a family with X-linked severe combined immunodeficiency (SCID) caused by an *IL2RG* mutation in the proximal long arm of the X chromosome *(marked with black bar)* is shown. Affected males have filled in square; female carriers are designated by dot in the center of their symbols. Two loci, one with alleles A and a, and the other with alleles B and b, are shown in the proximal and distal long arm of the X (Xq). There are no recombinations during female meiosis between allele a and the *IL2RG* mutation in any of the eight children, while three children *(marked with asterisk)* show a recombination with the locus on the distal Xq. The father's X chromosome is passed on without any recombinations to each of his daughters and is shown on the left of each pair of X chromosomes in the daughters.

Linkage analysis and association studies have limitations in investigating the genetic basis for human immunological disorders. Linkage analysis is problematic if the disorder is a rare autosomal recessive condition such that there are not enough families with two carrier parents to enable such a study; nonetheless, the increased frequency of consanguineous matings in some populations has been utilized to overcome this limitation.[23,24] Another challenge with linkage analysis is if the disorder is genetically lethal so that it is never inherited and always occurs sporadically as a result of a new mutation. Detecting an association in a case-control study is also a problem when the frequency of any particular allele associated with the disease is too low among the cases to give a detectable association. For example, if the disorder arises from different, independent mutations and if these mutations are found on many different haplotypes in affected individuals, it may be very difficult to establish a significant association with any one variant.

When linkage and association studies are not possible, as in very rare mendelian disorders, a third approach is now available—genome sequencing. Vastly improved methods of DNA sequencing have cut the cost of sequencing six orders of magnitude over what was spent generating the Human Genome Project's reference sequence, opening up new possibilities to discover the genes and mutations responsible for rare mendelian disorders. One can generate a whole-genome sequence (WGS) or, in what has often proven a cost-effective compromise, a sequence of only about

FIG 33.4 An Example of a Population-Based Genome-Wide Association Analysis——As a Means to Identify a Disease Gene. (A) A mutation (X) that predisposes to a disease first occurs on a chromosome with a certain set of alleles at polymorphic loci along that chromosome *(symbolized by the blue color).* With each generation, meiotic recombination exchanges the alleles that were initially present at polymorphic loci on the "blue chromosome" for other alleles present on homologous chromosomes *(symbolized by other colors).* Over many generations, the only alleles that remain associated with the mutation are those at loci so close to the mutant locus that recombination between them is very rare. These alleles constitute a disease-associated haplotype. (B) Affected individuals in the current generation (*arrows*) carry the mutation (**X**) are enriched for the disease-associated haplotype (*individuals in blue*) compared with unaffected individuals. Depending on the age of the mutation and other population genetic factors, a disease-associated haplotype ordinarily spans a region of DNA of a few kilobases to a few hundred kilobases. (From Nussbaum R, McInnes RR, Willard HF. Thompson and Thompson Genetics in medicine. 8th ed. Toronto, Canada: Elsevier Canada; 2016: 177, Fig. 10.8, with permission.)

2% of the genome, the part containing the exons of genes, referred to as a whole exome sequence (WES).

As an example of what is now possible, suppose that there is a family "trio" consisting of a child affected with a rare immunodeficiency and his or her parents. WES is carried out on the child and the parents, yielding typically over 4 million SNV, indel, and CNV differences in the child compared with the human genome reference sequence. Which of these variants would be responsible for the disease? The extraction of useful information from such a massive amount of data relies on creating a variant filtering scheme based on a variety of reasonable assumptions about likely responsible explanations for the disease.

One example of a filtering scheme that can be used to sort through these variants is shown in Fig. 33.5, in which exome sequence was performed for two parents and their offspring, two affected and one unaffected.

1. *Location with respect to protein-coding genes.* Keep variants that are within or near exons of protein-coding genes and discard variants deep within introns or intergenic regions. It is possible, of course, that the responsible mutation might lie in a noncoding RNA gene (*e.g., RMRP,* the gene mutated in the immunodeficiency and dwarfing syndrome cartilage hair hypoplasia). However, these are currently more difficult to assess, and thus, as a simplifying assumption, it is reasonable to focus initially on protein-coding genes.
2. *Population frequency.* Keep rare variants from Step 1 and discard common variants with allele frequencies <0.05 (or some other arbitrary number between 0.01 and 0.1) because common variants are highly unlikely to be responsible for a disease whose population prevalence is much less than the q^2 predicted by the Hardy- Weinberg equilibrium.
3. *Deleterious nature of the mutation.* Keep variants from Step 2 that cause nonsense or nonsynonymous changes in codons within exons, cause frame-shift mutations, or alter highly conserved splice sites. Discard synonymous changes that have no predicted effect on protein function (unless there is reason to suspect that they influence splicing or expression, such as the last nucleotide of an exon, which is typically "G").
4. *Consistency with likely inheritance pattern.* If the disorder is considered most likely to be autosomal recessive, keep any variants from Step 3 for which an affected child has 2 variants in the same gene and each parent has one of the variants.

FIG 33.5 **Variant Filtering Can Be Used to Sort Through Whole-Exome Sequence Analysis of a Familial Disease.** Protein-altering variants detected in the affected children, their unaffected sibling, and parents were first filtered by sequencing quality and allele frequency to yield a set of 88 rare, damaging or nonsynonymous variants that fit an autosomal recessive inheritance pattern and were then candidates for causing the autoimmune disorder. This group was then further analyzed for genes involved in immune function, which brought two variants in *ZAP-70,* for which the affected children were both compound heterozygotes, to the top of the list as possible causative mutations. (Adapted from Chan et al. A novel human autoimmune syndrome caused by combined hypomorphic and activating mutations in ZAP-70. J Exp Med 2016;213:155–65, with permission.)

The child need not be homozygous for the same deleterious variant but could be a compound heterozygote for two different deleterious mutations in the same gene.

In the example in Fig. 33.5, the two affected children were compound heterozygous for variants, with each parent and the unaffected sister carrying one of the variants. If there were consanguinity in the parents, the candidate genes and variants might be further filtered by requiring that the child be a true homozygote for the same mutation derived from a single common ancestor. If the autosomal recessive mode of inheritance is correct, then the parents should both be heterozygous for the variants. The disease-causing variant in a male could also be X-linked, in which case any variant found in an X-linked gene for which the mother is a heterozygote would be a candidate.

For either the autosomal or X-linked case, the disorder could be the result of a new dominant mutation; in this case, keep variants from Step 3 that are *de novo* changes in the child and are not present in either parent.

In the end, millions of variants can often be filtered down to a handful of SNVs, indels, or CNVs affecting a reasonable number of genes. Once the filtering reduces the number of genes and alleles to a manageable number, they can be assessed individually for other characteristics. Do any of the genes have a known function or tissue expression pattern that would be expected if it were the potential disease gene? Is the gene already implicated in other disease phenotypes, or does it have a role in pathways in which mutations are known to cause similar or different phenotypes? Finally, is the same gene mutated in other patients or in an animal model with the disease? Finding mutations in one of the candidate genes also in other patients would confirm that this gene was the responsible gene trio under study. In some cases, one gene remaining on the list in Step 4 may become a leading candidate because its involvement makes biological or genetic sense or it is known to be mutated in other affected individuals. In other cases, however, the gene responsible may turn out to be entirely unanticipated on biological grounds or may not be mutated in other affected individuals because of locus heterogeneity (*i.e.,* mutations in other as yet undiscovered genes can cause a similar disease).

Such variant assessments require extensive use of public genomic databases and software tools. These include the human genome reference sequence, databases of variants with their allelic frequencies, software that assesses how deleterious an amino acid substitution might be to gene function, collections of known disease-causing mutations, and databases of functional networks and biological pathways. The enormous expansion of this information over the past few years has played a crucial role in facilitating gene discovery of rare mendelian disorders.

In a recent report of the clinical use of WES in rare disorders,[25] 2000 individuals with a variety of disorders that had escaped diagnosis despite thorough conventional clinical evaluations underwent WES. A likely causative mutation or pair of mutations was found in 504 (25.2%). Of these mutations (of which many were severe developmental defects), half were *de novo,* not present in either parent. Also of interest was that 23 (4.6%) of these 504 patients in whom a diagnosis was made through WES had two different genetic disorders, resulting in a combined phenotype, most likely obscuring the diagnosis of either of the individual disorders had they been present alone.

In some cases, the difficulty in making a diagnosis was the result of there being a mutation in a gene, previously unknown to cause human disease, but implicated by finding mutations that fit the inheritance pattern (*de novo* dominant or autosomal recessive), and then later confirmed by finding other mutations in phenotypically similar patients. In others, the gene involved had been previously described, but not in association with the phenotype for which the patient was undergoing diagnostic exome analysis. For example, two children affected with an undiagnosed autoimmune syndrome consisting of early-onset bullous pemphigoid, nephritis, autoimmune antifactor VIII hemophilia, and inflammatory bowel disease. WES was performed for both children, their unaffected sister, and both unaffected parents.[26] Eighty-eight genes were found in which the two affected children were compound heterozygotes for two different rare mutations, whereas the unaffected sister and both parents were carriers for only one of the two mutations found in the children. Of these, only one gene was known to have any immunological function: *ZAP70,* previously known to be mutated in combined immunodeficiency but not with strictly autoimmune disease of this type (see Fig. 33.5). Both affected children were compound heterozygotes for two missense mutations, p.R192W and p.R360P, in *ZAP70.* The mother carried the R192W allele, whereas the father and unaffected sister carried the R360P allele. Neither mutation had been reported previously, nor were they near mutations in the same gene that had been previously associated with human disease. Functional studies revealed the p.R192W had reduced activity, whereas the R360P encoded a modestly hyperactive protein because of disruption of an autoinhibitory mechanism. The combination of these alleles, as proven in laboratory studies, fully explained the autoimmune phenotype.

ON THE HORIZON

- As the costs of deep sequencing fall, examination of whole-genome sequence should allow for examination of noncoding regulatory regions.
- Data storage and computer speed will need to be improved to handle 50-fold more data from each individual.
- New analytical paradigms for the analysis of variation in noncoding DNA and the interpretation of DNA variants that are not clearly associated with deleterious effects will be required.
- Proving causality of new gene variants in primary immunodeficiencies will depend on future cataloguing of deleterious mutations in each gene and on molecular studies of the direct effects of the variants.

Since the application of WGS or WES to rare mendelian disorders was first described in 2009, hundreds of such disorders have been studied and the causative mutations found in nearly 500 previously unrecognized disease genes.[27] The pace of discovery will only increase, and we can anticipate that the number of known mendelian disorders, including those characterized by primary immunodeficiency and/or autoimmunity, will grow over coming years. It has been predicted that the genetic basis for every human single gene disorder will be elucidated in the near future. However, the genetic basis for complex disorders that show increased familial occurrence, and yet are not single gene disorders and do not follow mendelian inheritance, remains elusive and will require another leap in technology and genetic analytical tools to be fully unraveled. The data being generated through human and model organism genomics will certainly aid in the elucidation of these more challenging disorders of the human immune system. New tools available to immunologists and geneticists will open great opportunities for discovery and understanding of genetic disorders of immunity which, in turn, will deepen our knowledge of immune system networks.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following variations in a gene expressed in T lymphocytes is MOST likely to be deleterious, capable of causing a human immune disorder if found in homozygosity:
   - **A.** A single nucleotide substitution AAA (lysine) ≥ TAA (stop) in an early exon of a gene required for T-cell receptor rearrangement
   - **B.** A single nucleotide substitution CTC (leucine) ≥ ATC (isoleucine) in a gene encoding a cytokine receptor
   - **C.** Deletion of 6 amino acids (CAACAA) in a short tandem repeat (STR) consisting of $(CAA)_{10}$ in the 3' untranslated portion of a gene expressed in all lymphocytes

2. True or False: A human inherited immunodeficiency caused by mutation of single gene can reliably be reproduced in the mouse by knockout of the orthologous murine gene.

3. DiGeorge syndrome is most commonly caused by:
   - **A.** A single nucleotide variation
   - **B.** A copy number variation
   - **C.** A retrotransposition
   - **D.** An indel mutation

Primary Antibody Deficiencies

Tracy Hwangpo, Harry W. Schroeder, Jr.

Primary antibody deficiency diseases are characterized by an inability of the humoral immune system to produce sufficient quantities of protective antibodies to properly protect the host from hazardous antigens.[1] This inability may be evident from birth, or it may manifest at a later age. In some cases, the deficiency may either resolve or worsen with time.[2] Many of these diseases are caused by mutations that alter the function of genes that regulate B-cell development or homeostasis. Others reflect mutations in the immunoglobulin (Ig) genes themselves. In some of the most common conditions, a genetic predisposition has been well documented, but the underlying defect remains unclear. The typical patient will present with a history of recurrent upper or lower respiratory infections and reduced serum concentrations of one or more classes of immunoglobulin (IgM, IgG, or IgA). However, patients with normal serum Ig levels may exhibit specific deficits in their ability to mount a protective response against certain antigens, and some patients with agammaglobulinemia can be remarkably asymptomatic. A classification of primary antibody deficiency diseases can be found in Table 34.1.

Primary immune deficiency disorders are the consequence of specific defects in B-cell development (Chapter 7). B-cell production begins in the fetal liver and shifts to bone marrow in the latter stages of fetal life (Fig. 34.1). As B cells mature, they leave the liver and bone marrow and migrate via blood into secondary lymphoid organs, including spleen, lymph nodes, and other peripheral and mucosal tissues. Contact with a polymeric cognate antigen, such as a polysaccharide, can activate the B cell and allow it to differentiate into an antibody-producing plasma cell. In contrast, the response to protein antigens, including toxins and viral proteins, requires T-cell help. In the germinal centers, B cells can replace an upstream heavy (H) chain constant domain with a downstream one (*e.g.*, μ to γ1), altering effector function (Chapter 15). They can also introduce mutations at a high level into the variable (V) domains, tailoring the antibody to the antigen, a process termed *affinity maturation.*

CLINICAL MANIFESTATIONS

Patients with antibody deficiencies most commonly present with a history of recurrent sinusitis, bronchitis, and pneumonia. Patients can also present with recurrent cellulitis, boils, gastrointestinal (GI) discomfort, myalgias, arthralgias, fatigue, and depression. The respiratory infections typically involve encapsulated bacterial pathogens, such as *Streptococcus pneumoniae* and *Haemophilus influenzae.* Protection against these bacteria requires production of antipolysaccharide antibodies, which does not require T-cell help. Because a similar susceptibility for infection is seen among patients that are deficient in neutrophil function or in the pivotal third component of complement (C3), all three of these arms of the host defense system should be evaluated in patients who suffer with recurrent bacterial infections.

CLINICAL PEARLS

Clinical Manifestations of Antibody Deficiency

- Recurrent bacterial infections
  - Early in untreated disease, infections are primarily caused by encapsulated pyogenic bacteria (*e.g., Streptococcus pneumoniae* and *Haemophilus influenzae* type b).
  - Later in untreated disease, damage to mucosal surfaces engenders susceptibility to staphylococci, nontypable *H. influenzae,* and gram-negative rods, as well.
- Recurrent viral infections
  - In most cases, viral infections are cleared normally, but protective immunity does not develop. For example, recurrent shingles can be a common symptom in untreated patients.
  - In some cases, patients may continue to excrete virus after resolution of their clinical symptoms.
- Increased prevalence of other immunological disorders
  - Paradoxical increased risk of antibody-mediated autoimmune disorders, such as idiopathic thrombocytopenia, autoimmune thyroiditis, systemic lupus erythematosus, and celiac disease.
  - Lymphoid hypertrophy
  - Increased risk of allergic disorders, especially among patients with IgA deficiency.

The clinical course of uncomplicated primary infections with viruses, such as varicella zoster or mumps virus, does not differ significantly from that of the normal host. However, patients with antibody deficiency have difficulty generating long-lasting immunity; thus chickenpox can repeatedly recur as shingles. The general rule is that T cells typically control established viral infections, whereas antibodies limit initial viral dissemination and cell entry, thereby preventing reinfection. As with all rules, there are exceptions. Patients with hypogammaglobulinemia can have difficulty clearing hepatitis B virus from the circulation, poliovirus from the gut, and enterovirus from the brain, leading to progressive and sometimes fatal outcomes.

Because sinopulmonary infections are also commonly seen in normal infants and children, in individuals with allergies, in smokers, and in patients with other diseases, such as cystic fibrosis, the threshold for an extensive evaluation for immunodeficiency can be a matter of clinical judgment. However, two or more episodes of bacterial pneumonia within a 5-year period, unexplained bronchiectasis, *H. influenzae* meningitis in an older child or adult, chronic otitis media in an adult, recurrent intestinal

infections and diarrhea caused by *Giardia lamblia,* or a family history of immunodeficiency all warrant evaluation by an immunologist.

The purest forms of antibody deficiency result from mutations that prevent the expression or function of the pre–B-cell receptor (Chapter 4). For example, a function-loss mutation of μ heavy chain or components of the surrogate light chain [VpreB, λ14.1 (λ5)] have been found to affect only the B-cell lineage. However, most of the diseases associated with primary antibody deficiency involve more than one cell lineage. For example, *X-linked agammaglobulinemia* (XLA) is the product of loss-of-function mutations in Bruton tyrosine kinase (BTK). Patients with *X-linked hyper-IgM syndrome* (HIGM1) may also exhibit T-cell dysfunction, placing them at risk for infection with *Pneumocystis jiroveci.* Immune deficiency also appears to place patients at risk for autoimmunity, which is increased among patients with *IgA deficiency* (IgAD), *common variable immunodeficiency* (CVID), and HIGM1.

Clinical manifestations of the primary immunodeficiency can also be heavily influenced by the patient's past medical history. A delayed diagnosis and failure to treat infections aggressively can lead to permanent damage to the respiratory or GI mucosa, thus creating susceptibility to nontypable *H. influenzae,* staphylococci, *Pseudomonas* spp., and enteric bacteria.

PRINCIPLES OF DIAGNOSIS AND TREATMENT

Diagnostic Tests and Their Interpretation

Testing for immune deficiency should be performed when the patient has a history of repeated infections that exceeds

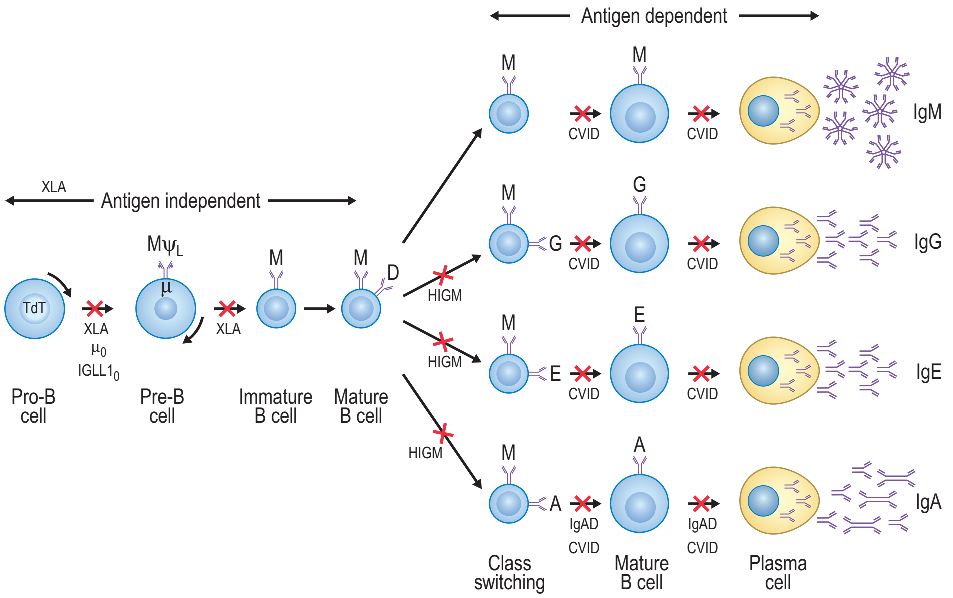

FIG 34.1 Defects in B-Cell Development Can Lead to Humoral Immune Deficiency. X-linked agammaglobulinemia (XLA) and autosomal agammaglobulinemias (AGMs) result from either a failure to generate a functional antibody receptor signaling complex or a failure to transmit signals from this complex. These failures obstruct production of immature B cells. Hyper-IgM syndrome (HIGM) results from either a failure to engage in proper cognate interactions with T cells or disruptions in the genes that permit class-switch recombination or somatic hypermutation. These failures inhibit class switching to IgG, IgA, and IgE, as well as limiting affinity maturation. Common variable immune deficiency (CVID), IgG subclass deficiencies (IgSD), selective IgA deficiency (IgAD), and transient hypogammaglobulinemia of infancy (THI) reflect a selective or generalized failure to progress from the immature B-cell stage to the plasma cell stage.

KEY CONCEPTS

Hypogammaglobulinemia and Antibody Deficiency

- The genetic mutations that underlie most primary antibody deficiencies tend to affect genes that play key roles in the regulation of lymphocyte development and homeostasis. Clinically significant antibody deficiency is not synonymous with hypogammaglobulinemia.
  - Serum immunoglobulin (Ig) concentrations vary widely with age.
  - Serum immunoglobulin levels vary with exposure to drugs (*e.g.*, steroids), infectious agents, and other environmental stressors.
  - A complete absence of IgG subclasses resulting from homozygous deletions of heavy-chain genes has been observed in healthy individuals.
  - Absence of a specific Vκ gene segment has been associated with an increased risk of *H. influenzae* infection in spite of normal serum Ig levels.

expectations for normal individuals, when an opportunistic pathogen or one of a low virulence is responsible for an infection, when a diagnosis of a disorder frequently associated with immunodeficiency has been made, or when there is a family history of primary immunodeficiency. Table 34.2 illustrates four levels of testing complexity and when such testing might commonly be undertaken.

Level I testing is both revealing and cost effective. It includes measuring serum Ig (IgM, IgG, and IgA), complement (50% hemolytic power of serum [CH_{50}] and complement components C3, C4, and mannose-binding lectin protein [MBL]), a complete blood count with differential (CBC/diff), and an erythrocyte sedimentation rate (ESR). Lymphopenia is found most often in disorders that affect the production or function of T cells (Chapter 35) but can also occur in patients with CVID. Congenital absence of an individual complement component will result in total absence of measurable complement-mediated hemolysis (Chapter 21). MBL deficiency increases susceptibility to respiratory infections.[3] The ESR is often, although not always, elevated in individuals with inflammatory disorders and can be useful in the evaluation of patients with a questionable or unclear history of recurrent or chronic infection.

KEY CONCEPTS

Testing for Immune Function

Testing for immune function should be performed:
- When the patient's history suggests a rate or severity of infection that exceeds normal expectations
- When the organism responsible for infection is of low virulence or is considered to be an opportunistic pathogen
- When there is a diagnosis of a genetic syndrome or disorder associated with immune deficiency either in the patient or in the patient's family

Interpretation of the significance of the quantitative Ig determinations requires appreciation of age-related changes in Ig concentrations (Fig. 34.2).[4,5] At the end of the second trimester of pregnancy, active transport of IgG across the placental barrier

TABLE 34.2 Laboratory Diagnosis of Primary Antibody Deficiency

Level	Test	Application(s)
I	CBC with differential Complement (CH$_{50}$, C3, C4, mannose-binding lectin [MBL] protein) Erythrocyte sedimentation rate (ESR) Quantitative serum immunoglobulin (Ig)M, IgG, and IgA levels	Primary screening tests
Ia	Urinalysis, 24-hour urine for protein Stool for α-1-antitrypsin	Symptoms suggest protein loss through kidneys or gastrointestinal (GI) tract
II	B-cell functional evaluation Quantitative IgG subclasses, IgE Natural or commonly acquired antibodies (isohemagglutinins, rubella, rubeola, tetanus) Response to immunization T cell–dependent antigens (tetanus) T cell–independent antigens (unconjugated pneumococcal vaccine, unconjugated *H. influenzae* B vaccine)	Level I normal but history suggests Antibody deficiency Better definition of a level I defect
III	Quantification of blood T-and B-cell subpopulations by immunofluorescence assays using monoclonal antibody markers T cells: CD3, CD4, CD8 B cells: CD19, CD20, CD21, Ig (μ, δ, κ, λ),	Panhypogammaglobulinemia or severely low IgM and IgA
IV	Disease-specific analysis Gene expression Gene sequencing	Gene-specific diagnosis Genetic counseling

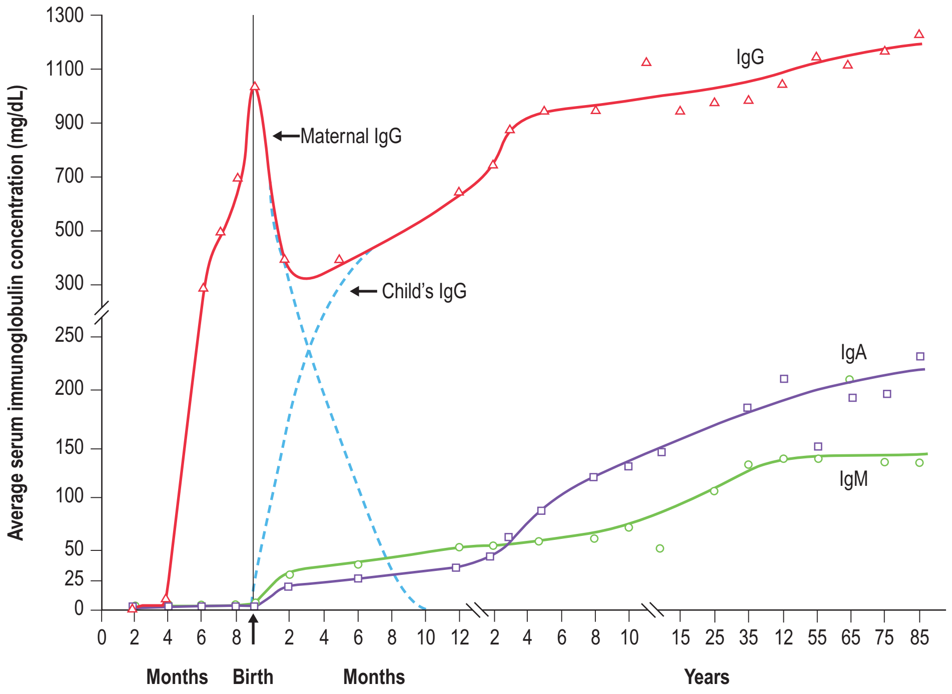

FIG 34.2 Age-Related Changes in the Serum Concentration of Immunoglobulins (Ig). Shown are average serum immunoglobulin concentrations of the major isotypes as a function of age.[4,5]

begins and, at birth, the infant's serum IgG concentration is typically 20–25% higher than that of the mother. Catabolism of maternal IgG coupled with the slow development of endogenous antibody function leads to a physiological nadir of serum IgG in infants of 4–6 months of age. In normal infants, this loss of maternal protection is often associated with the first appearance of otitis media or bronchitis. Thus the onset of sinopulmonary infections within the first 3 months of age should also raise the index of suspicion for immunodeficiency in the mother. After age 6 months, maternally-derived IgG has largely been lost, and IgG antibodies specific for diphtheria or tetanus become useful functional measures.

IgM is the first isotype to reach young adult levels, followed by total IgG and then IgA. This physiological delay in the production of serum IgA can complicate the diagnosis of IgA deficiency in infants and young children. Serum Ig concentrations in healthy adults tend to remain remarkably constant but can increase dramatically in response to infection and suffer a decline in response to immunosuppressive agents, such as corticosteroid administration. With increasing age, serum immunoglobulin

CLINICAL PEARLS

Interpreting Quantitative Immunoglobulins (Igs)

- Normal ranges of serum immunoglobulin levels vary with age (Appendix 2); hence evaluation should take the age of the patient into account.
  - As the mother's transplacental contribution of IgG is catabolized, total serum IgG concentrations reach a nadir at 4–6 months of age
  - IgG2 and IgG4 subclass levels rise more slowly than IgG1 and IgG3; hence reference to adult controls can lead to the false diagnosis of IgG subclass deficiency in young children.
  - Serum IgA concentrations typically do not achieve adult values until puberty. They are often the first to decline in many primary immunodeficiencies

may continue to rise.[4] The physiological significance of this increase in older adults is unclear, although in some cases it reflects an accumulation of expanded B-cell clones or monoclonal gammopathies (Chapter 80).

KEY CONCEPTS

Functional Tests of Specific Antibody Production

- Immunoglobulin M (IgM) T-independent responses can be assessed by measurement of serum isohemagglutinins (anti-A and anti-B titers) in patients who are not blood type AB.
- IgG T-independent responses can be assessed by measurement of antibodies produced in response to immunization with unconjugated purified pneumococcal polysaccharide vaccine.
- IgG T-dependent recall responses can be assessed by measurement of ≥4-fold rise in titer of antibodies to diphtheria or tetanus toxoid alter booster immunization.

The common laboratory practice of defining the lower range of normal for serum Ig levels as two standard deviations below the age-adjusted mean carries with it the risk of falsely labeling otherwise normal patients as having immunodeficiency. Ig levels vary widely with environmental exposure, and normal biological variation is much broader than that defined by the mean of the population. Patients with a combined deficiency of IgA and an IgG subclass may benefit from more aggressive therapy; thus quantitative measurements of all four IgG subclasses—IgG1, IgG2, IgG3, and IgG4—can be useful in fully defining the extent of humoral immune deficiency.

Among patients with borderline serum IgG levels, tests to evaluate the host's ability to produce functional specific antibody should be performed before making a decision to institute a more aggressive therapy, especially among patients receiving corticosteroids, which can lower total serum IgG while preserving function. The most commonly employed tests include measurement of isohemagglutinins (naturally occurring IgM antibodies to the polysaccharide antigens that define the ABO blood type system on red blood cells [RBCs]) and postimmunization responses to polysaccharide antigens (*e.g.,* Pneumovax23 or unconjugated *H. influenzae B* vaccine) and protein antigens (*e.g.,* tetanus or diphtheria toxoids). IgM is made by the newborn, and most infants can generate isohemagglutinins, making determination of anti-A and anti-B titers a useful measurement of B-cell function even in infants. In older children and adults, isohemagglutinin titers <1 : 8 are considered significantly decreased.[6]

Serum for specific antibody titers should be obtained before and 4–6 weeks after immunization. Optimally, the paired sera should be assayed simultaneously to avoid confusion that may result from single-tube dilution differences at the time the assay is performed. As a general rule, a high baseline titer or ≥4-fold rise in a specific titer in individuals with a low baseline titer confirms that a specific humoral response is intact. The development of conjugated polysaccharide vaccines complicates analysis for those who have received such a vaccine, although information can still be gleaned from study of responses to polysaccharide antigens present only in multivalent unconjugated vaccines.

Because of its relatively low molecular weight and slow turnover compared with other isotypes, protein loss through the kidneys or GI tract can result in the selective loss of IgG. Should symptoms warrant, 24-hour urine for protein or a stool sample for alpha-1-antitrypsin level can document protein loss.

An elevated IgE level may support a suspicion of allergy as an underlying explanation of sinopulmonary symptoms. Serum IgE concentrations are often elevated in patients with IgA deficiency. Extreme elevations of IgE suggest the *hyper-IgE syndrome.*

Enumeration of B cells and of T cells should be performed for any individual who has severe panhypogammaglobulinemia. The most widely used method of demonstrating B cells relies on immunofluorescent labeling of surface CD19, which is restricted in expression to mature B cells. Because an infant may have serum IgG of maternal origin for the first several months of life, the determination of the number of circulating B cells is the single most useful test in making the presumptive diagnosis of XLA, a disorder in which pre-B cells in bone marrow fail to develop to cells of mature phenotype. Absence of circulating B cells also characterizes the *immunodeficiency associated with thymoma* in adults, whereas adults with *chronic lymphocytic leukemia* may have hypogammaglobulinemia with an overabundance of circulating B cells that typically express CD5.

HIGM1 represents the product of a loss-of-function mutation of the *CD154* (*CD40L*) gene. CD154, a surface antigen found on activated T cells, binds CD40 on B cells to facilitate class switching, survival, and proliferation (Chapter 8). A fluorescent-labeled CD40 fusion protein can be used to evaluate the expression of functional CD154 on T cells by flow cytometry. Confirmation of the diagnosis, carrier detection, and prenatal diagnosis often depend on molecular or sequence analysis of the gene.

Replacement Therapy With Human Immunoglobulin

There are a number of commercial preparations of human Ig that are approved by the US Food and Drug Administration (FDA) and available in the United States (Chapter 84). No commercial preparations in this country are available to supplement IgM or IgA exclusively, but some of the preparations contain minute amounts. All commercial human Ig preparations are effective in treating patients with immunodeficiency disorders. Clinically relevant differences relate to the route of administration, which can be by intravenous or subcutaneous means, to the method of stabilization and storage, and to quantities of contaminating serum IgA in the preparations. Low IgA content is a concern for those rare individuals with immunodeficiency and absent IgA, who manufacture IgG or IgE antibodies directed against IgA and have a history of anaphylactic reactions upon infusion of IgA-containing blood products.[7]

Ig replacement therapy is not indicated for patients whose immune deficiency is limited to the selective absence of IgA because of the risk of anaphylaxis upon receipt of IgA-containing products, even though such reactions are extremely rare.[7] However, Ig replacement therapy has been found to be beneficial in patients with a combined deficit of IgA and IgG subclasses who exhibit impaired antibody responses to carbohydrate antigens.

The goal of Ig replacement is to provide sufficient concentrations of functional antibodies to prevent disease, not to achieve a target IgG level in the serum. Specific approaches to and protocols for Ig replacement therapy are described in detail in Chapter 84. Note: *The only indication for immunoglobulin replacement in a patient with immunodeficiency is severe impairment of the ability to produce functional antibody.* Such impairment exists in primary immunodeficiency diseases associated with low levels of all five isotypes of immunoglobulin, such as XLA, CVID, HIGM, and *severe combined immunodeficiency* (SCID) (Chapter 35). Patients with a documented inability to produce specific antibodies after immunization with a history of significant morbidity from infections are also candidates for intravenous immunoglobulin (IVIG) therapy even though they may present with normal or near-normal levels of IgG.[8] This includes certain cases of IgG subclass deficiency, such as those associated with compound IgA, IgG2, and IgG4 deficiency, boys with Wiskott-Aldrich syndrome, and patients with ataxia–telangiectasia. Since most patients with transient hypogammaglobulinemia of infancy can produce normal amounts of specific antibodies after immunization despite having a low total serum IgG, they usually are not candidates for Ig replacement although those patients with a history of significant infections may benefit.

X-LINKED AGAMMAGLOBULINEMIA

Diagnosis

XLA, also known as Bruton agammaglobulinemia, is the prototypic humoral immunodeficiency.[9] Function-loss mutations in *BTK* lead to a block in B-cell maturation, a near total absence of B cells in the periphery, and panhypogammaglobulinemia. As a result of the transplacental transfer of maternal Ig, affected boys typically do not begin to suffer recurrent pyogenic infections until after age 6 months. The normal delay in endogenous Ig production and the presence of maternal IgG requires that testing of infants known or suspected to have XLA should begin with examination of the number of B cells in blood. Deficient expression of BTK protein can be detected by flow cytometry, a technique that can also be used for carrier detection. For those cases where protein is present but the phenotype suggests XLA, analysis of the *BTK* gene at the nucleotide level remains the definitive diagnostic procedure. As with most X-linked lethal diseases, approximately one-third of sporadic cases are caused by *de novo* mutations, and diagnosis may require individual mutation analysis. There can be significant variation in the manifestations of the disease in any given family member; thus a paucity of symptoms should not prevent diagnostic evaluation even in adults.[10] Some cases of XLA have been reported with mild mutations that cause infections late in life.[11]

Clinical Manifestations

Although patients begin to suffer recurrent infections by age 1 year, with antibiotics and good hygiene, it is not uncommon to delay suspicion of the diagnosis well into mid-childhood. Indeed, diagnoses have been made in older adults, including aged male relatives of affected probands.[10,11] Recurrent upper and lower respiratory tract infections are common. Untreated, these infections may lead to bronchiectasis (Fig. 34.3), pulmonary failure, and death at an early age. The infections are typically caused by pyogenic encapsulated bacteria. Diarrhea caused by *G. lamblia* is also common, although less so than in CVID. Systemic infections include bacterial sepsis, meningitis, osteomyelitis, and septic arthritis. *Mycoplasma* and *Chlamydia* infections of the urogenital tract may lead to epididymitis, prostatitis, and urethral strictures. Skin infections include cellulitis, boils, and impetigo.

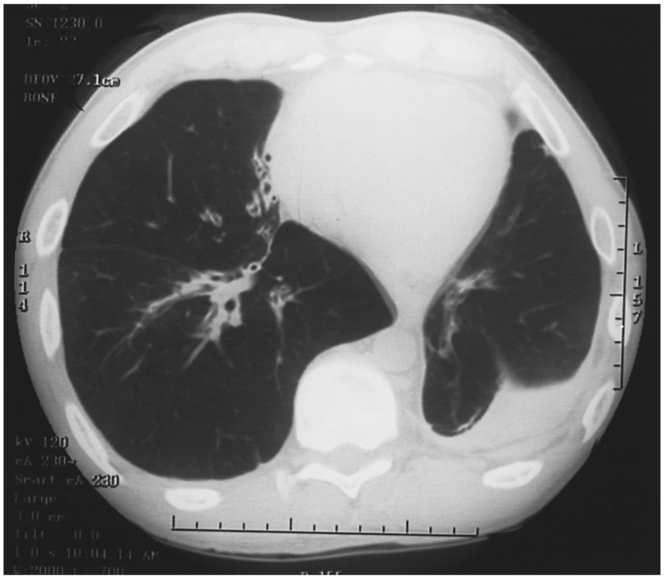

FIG 34.3 A Computed Tomography (CT) Scan, With Contrast, Demonstrates Bronchiectasis, Bronchitis, and Emphysema in the Lungs of a 36-Year-Old Man With X-Linked Agammaglobulinemia (XLA). Because of a left lower-lobe lobectomy, the mediastinum has shifted to the left. As a result of bronchiectatic scarring, the diameter of the bronchi in the right lung is greater than the diameter of the corresponding blood vessels, and the bronchi remain dilated in the periphery. Bronchial plugs can be seen filling some of the bronchi on the right. Finally, as a result of emphysema, the right upper lobe demonstrates greater radiolucency. In addition to suffering from XLA, this patient has a 30 pack-year history of smoking, which has exacerbated his clinical condition.

Although in patients with XLA most viral infections can be resolved, these patients are unusually sensitive to infections with enteroviruses. Patients with XLA can develop paralytic poliomyelitis after vaccination with live virus. Echovirus and Coxsackie virus infections may involve multiple organs with the patients going on to develop chronic meningoencephalitis, dermatomyositis, and/or hepatitis.

Untreated patients often complain of arthritis affecting the large joints. This appears to have an infectious etiology because the arthritis typically resolves with Ig replacement therapy. Enterovirus and mycoplasma have been identified in the affected joints of these patients.

Infections with opportunistic organisms, such as *Mycobacterium tuberculosis, Histoplasma,* and *P. jiroveci,* and malignancies are rare, likely reflecting intact cell-mediated immunity.

Origin and Pathogenesis

BTK belongs to a subfamily of the Src cytoplasmic protein-tyrosine kinases. BTK is phosphorylated following activation of the B-cell receptor (BCR). It plays a critical role in the proliferation, development, differentiation, survival, and apoptosis of

B-lineage cells. Individuals with XLA begin with normal numbers of early B-lineage progenitors in their bone marrow. These B-cell progenitors express the expected markers of B-cell differentiation, including terminal deoxynucleotidyl transferase (TdT), CD19, and CD10. There is, however, a relative deficiency of cells containing cytoplasmic μ heavy chains in bone marrow. Development of cells beyond the pre–B stage is even more severely impaired. Those cells that make it through the gauntlet can produce antigen-specific antibodies. Although present in low numbers, these B cells in lymphoid tissues enable XLA patients to express endogenous Ig, class switch, and even suffer allergic or autoantibody-mediated reactions.

Patients have been described with an X-linked recessive form of agammaglobulinemia that is associated with growth hormone deficiency. Genetic analysis of the *BTK* gene in one such patient identified a frameshift mutation leading to a premature stop codon and the loss of carboxy-terminal amino acids.[12]

Treatment and Prognosis

The primary goal of therapy is to prevent damage to the lungs. Human Ig replacement therapy should be started as soon as the diagnosis is made (Chapter 84). Patients treated with sufficient quantities (0.4–0.6 g/kg every 3–4 weeks for IVIG or 100–150 mg/kg every week for subcutaneous immunoglobulin [SQIG]) suffer few lower respiratory tract infections. However, these patients remain at risk for viral infections, including enteroviral meningoencephalitis. Since mucosal Ig cannot be replaced, the patients also remain at risk for recurrent upper respiratory infections, which may require prophylactic antibiotic therapy. Ig-treated patients may lead normal lives without concern about exposure to infectious agents in childcare settings or classrooms.[13] Immunizations of any type are unnecessary because the monthly replacement therapy will provide passive protection. Since patients are unable to mount antibody responses, vaccines, especially live vaccines, carry some risk of untoward side effects, so these vaccines are relatively contraindicated.

A patient with XLA who develops symptoms of enteroviral central nervous system (CNS) or neuromuscular infection should have appropriate culture of the involved organ system. For patients with agammaglobulinemia who have chronic enteroviral infections, Ig therapy should be given at higher doses and maintained until symptoms cease and the virus can no longer be detected.

AUTOSOMAL AGAMMAGLOBULINEMIA

Origin and Pathogenesis

The Pre–B-Cell Receptor and Signal Transduction Axis

Expression of the pre-BCR is a key step in the maturation of the pre–B cell[14] (Chapter 7). Function-loss mutations in any one of the genes that code for components of the pre-BCR and its associated signaling complex can inhibit pre–B-cell development, leading to an absence of mature B cells. This phenotype is seen in patients with biallelic function-loss mutations of the μheavy chain region (μ_0, AGM1), the λ-like surrogate light chain (IGLL1, AGM2), the Ig-associated α (Igα, CD79A, AGM3) and -β(Igβ, CD79B, AGM6) chains, and the adaptor B-cell linker protein (BLNK, AGM4), which is a key cytoplasmic component of the pre-BCR signaling pathway.

TCF3

The *TCF3* gene, also called *E2A*, encodes 2 basic helix-loop-helix (bHLH) transcription factors, E12 and E47, through alternative splicing. E12 and E47 are involved in regulation of immunoglobulin gene expression. A mutation in the DNA-binding region of E47 has been shown to result in agammaglobulinemia as a result of a dominant negative early block in B-cell development.[15]

LRRC8

An absence of B cells has also been reported in a young female patient with a truncation of leucine-rich repeat containing 8 (*LRRC8*, AGM5),[16] a gene of unknown function that is expressed in patients with progenitor B cells.

PIK3R1

A homozygous nonsense mutation in the *P1K3R1* gene, encoding the p85a subunit of phosphoinositide 3-kinase (PI3K), was found in a 19-year-old female with agammaglobulinemia, absent B cells, and inflammatory bowel disease by exome sequencing. The loss of p85a resulted in decreased pro–B cells, a contrast to the other agammaglobulinemia defect, which is localized to the pre–B-cell stage.[17]

Diagnosis and Treatment

Diagnosis in each of these cases requires gene mutation analysis. Treatment follows the same guidelines given for XLA.

HYPER-IGM SYNDROME

Diagnosis

Patients with the HIGM syndrome exhibit markedly reduced serum concentrations of IgG, IgA, and IgE with normal to elevated levels of IgM and normal numbers of circulating B cells.[18] The altered distribution of Ig isotypes reflects a block in the ability of B lymphocytes to switch from IgM to the other isotypes. Increased IgM reflects polyclonal expansion of IgM synthesis in response to infection. Patients with HIGM suffer from the same infections with encapsulated bacteria common to all patients with antibody deficiency. The HIGM phenotype can be inherited as an X-linked, autosomal recessive, or autosomal dominant trait. The phenotype can also be acquired in association with neoplasia or congenital rubella.

HIGM Syndrome Type 1: CD40L (CD154) Deficiency

Class switch recombination is a multistep process that requires exquisite coordination between the B cell and its cognate T-helper (Th) cell. A key step in the initiation of the process is the binding of constitutively expressed CD40 on the B cell to its ligand, CD40L (CD154), which is expressed on activated T cells. The most common form of the disease, X-HIGM1, results from loss-of-function mutations in *CD154* (Xq26).

HIGM Syndrome Type 2: AID Dysfunction

Activation-induced cytidine deaminase (AID; 12p13), a member of the cytidine deaminase family, is required for class switch recombination between Ig H chain constant domains and for somatic hypermutation of the Ig V domains (Chapter 4). The hyper-IgM phenotype (HIGM2) can result from either biallelic *AID* function-loss mutations or from a dominant negative mutation on only one of the *AID* alleles.

HIGM Syndrome Type 3: CD40 Deficiency

The cognate partner for CD40L (CD154) is CD40, the gene for which (*CD40*) is located on an autosome (20q12-q13.2). Patients with HIGM3 with function-loss mutations on both alleles of the *CD40* gene present with a phenotype indistinguishable from HIGM1.

HIGM Syndrome Type 4: As yet Unknown Causes

Patients presenting with a HIGM-like phenotype, but lacking demonstrable mutations in genes previously associated with HIGM, such as *CD40, CD154, NEMO, AID,* and *UNG,* have been grouped by some immunologists into a category termed *HIGM4.* B cells from patients with HIGM4 demonstrate defective class switch recombination, but normal somatic hypermutation. A genetic cause has yet to be identified, and spontaneous recovery has been reported.[19]

HIGM Syndrome Type 5: UNG Deficiency

Activation-induced cytidine deaminase (AID) acts by deaminating cytidine nucleotides in DNA, leaving a uracil nucleotide in its place. Uracil-DNA glycosylase (UNG; 12q23-24.1) can remove the uracil, permitting normal or error-prone repair. Patients with function-loss mutations on both alleles of the *UNG* gene (HIGM5) have presented with a history of bacterial infections, hyperplasia, increased serum IgM levels, and low IgG and IgA.

NEMO

The nuclear factor κB (NF-κB) essential modulator (NEMO) plays a key role in the NF-κB pathway and consequently in the CD40 signal transduction pathway. NEMO acts as a scaffold for two kinases important for the activation of NF-κB. The *IKBKG* gene encodes for NEMO and is located on the X-chromosome (Xq28). Hypomorphic mutations in the gene causes a syndrome with affected individuals having ectodermal dysplasia. This results in conical teeth, an absence of eccrine sweat glands, and a paucity of hair follicles. Patients with NEMO are considered to have a defect in innate immunity and cell-mediated immunity as a result of defective NF-κB activation, which is important in Toll-like receptor (TLR) signaling. Laboratory abnormalities include impaired natural killer (NK) cell function, impaired pneumococcal responses, hypogammaglobulinemia, antigen-specific T-cell proliferative abnormalities, and increased serum IgA levels. Less than 20% of patients with NEMO have HIGM and, thus in the past, have been grouped with the HIGM group.[20]

Clinical Manifestations

CD40-CD154 Axis (HIGM1, HIGM3, NEMO)

The majority of patients with HIGM have inherited disruptions in the CD40-CD154 axis. Lymph nodes and spleen are deprived of germinal centers. Recurrent upper and lower respiratory tract infections are the most common clinical complaint. Patients may also exhibit recurrent neutropenia with oral ulcers, perirectal abscesses, and opportunistic infections with *P. jiroveci, Toxoplasma gondii,* or *Cryptosporidium* cholangitis. Autoimmunity is observed in approximately 20% of patients.

Without prophylaxis, one third of patients develop *P. jiroveci* pneumonia, which can be the presenting problem in affected infants. These patients are also at risk for serious infections with cytomegalovirus (CMV), adenovirus, *Cryptococcus neoformans,* or mycobacteria. These features signal a compromise in cell-mediated immunity as well as the characteristic flaw in antibody production, putting them in the spectrum of a combined immunodeficiency.

Chronic diarrhea occurs in more than half of the patients. Organisms include *Cryptosporidium, G. lamblia, Salmonella,* and *Entamoeba histolytica.* One quarter may require total parenteral nutrition because of the presence of diarrhea or perirectal abscesses. Oral ulcers, gingivitis, and perirectal ulcers are associated with neutropenia, which may occur chronically or intermittently in up to two-thirds of the patients. One-fifth of the patients develop sclerosing cholangitis that can lead to hepatic failure. Cryptosporidiosis is present in half of these patients.

Approximately one-quarter of patients with NEMO have autoimmunity or autoinflammation. An intestinal inflammatory disorder may be the presenting problem with chronic diarrhea and abdominal pain, with a few having steroid dependence.

Although originally distinguished by the high level of serum IgM, IgM levels are often normal in affected individuals. IgG is low in all patients. IgA and IgE are usually low but can be normal or even elevated in one-tenth of the population. B- and T-cell counts are within the normal range in more than 90% of the patients and depressed in the rest.

Lymphoid hyperplasia is a common finding in CD40–CD154 axis patients with active infections. Individual nodes may become extremely large, and some patients develop splenomegaly. Hilar adenopathy causes a diagnostic dilemma, as the risk of lymphoma is increased in HIGM. Although the lymphoid tissue is usually histologically abnormal, reactive processes are far more common than malignancy. Plasma cells can be abundant or sparse. Primary follicles are poorly developed. The most characteristic abnormality is the absence of germinal centers.

AID–UNG Axis (HIGM2 and HIGM5)

Infected patients with AID–UNG deficiency may present with giant germinal centers filled with highly proliferating B cells, presumably as a result of intense antigen stimulation. Approximately one-fourth of patients with HIGM2, but not HIGM5, present with evidence of autoimmunity. Manifestations include hemolytic anemia, thrombocytopenia, and autoimmune hepatitis. Autoantibodies in these patients are of the IgM isotype.

Origin and Pathogenesis

CD40–CD154 Axis (HIGM1, HIGM3, and NEMO)

CD154, a member of the tumor necrosis factor (TNF) family, is a type II transmembrane protein that is predominantly expressed on mature, activated CD4 T cells. Its expression peaks at 6–8 hours after activation and then falls to resting levels by 24–48 hours. CD154 is also expressed on CD4 thymocytes, activated CD8 T cells, NK cells, monocytes, basophils, mast cells, activated eosinophils, and activated platelets. Newborn T cells are deficient in CD154 expression, although they can be induced to express the antigen if strongly stimulated.

CD40 is a member of the TNF receptor superfamily. It is constitutively expressed on pro-B, pre-B, and mature B cells, as well as on interdigitating cells, follicular dendritic cells (DCs), thymic epithelial cells, monocytes, platelets, and some carcinomas.

Engagement of B-cell CD40 with CD154 on an activated T cell that also expresses Fas ligand (FasL or CD95L) leads to the upregulation of Fas (CD95) on the B cell. NEMO is a part of the signaling pathway. If the B cell has concomitantly bound its cognate antigen and engaged the BCR-signaling pathway, it becomes resistant to Fas-mediated apoptosis and expresses CD80/CD86 on the cell surface. The activated B cell can then engage CD28 on the T-cell surface and trigger the T cell to secrete its cytokines. If the B cell fails to engage its BCR, the Fas pathway predominates, and the B cell is eliminated. With proper activation of the CD40–CD154 pathway, exposure to interleukin-2 (IL-2) and IL-10 induces production of IgM, IgG1, and IgA; and exposure to IL-4 induces production of IgG4 and IgE. This change in Ig isotype reflects both induction of switching and the enhanced survival and proliferation of the B cell. In the absence of CD154, B cells can express IgM but have difficulty switching and are likely to undergo apoptosis, rather than proliferate in response to antigen.

CD40–CD154 interactions between $CD154^+$ T cells and $CD40^+$ macrophages lead to enhanced production of IL-12, which then stimulates T cells to release interferon-γ (IFN-γ). Activation of this pathway appears necessary for the defense against *P. jiroveci* and other opportunistic organisms.

Treatment and Prognosis

The availability of human Ig replacement therapy has greatly improved the quality of life in patients with HIGM. Adequate replacement can result in the reduction of serum IgM concentrations, prevention of infections with encapsulated bacteria, resumption of growth, and the gradual resolution of splenomegaly and lymphoid hyperplasia. Autoimmune and lymphoproliferative complications may respond to anti-CD20 therapy (rituximab).[21]

Unfortunately, in spite of the improvement gained by Ig replacement, the prognosis of patients with defects in the CD40–CD154 axis remains guarded. Death at a young age continues to be common. It is primarily the result of opportunistic infections, including *Pneumocystis* pneumonia, cholangitis, CMV infection, mycobacterial infections, and cirrhosis secondary to hepatitis. Prophylaxis with trimethoprim–sulfamethoxazole can significantly reduce the risk of *Pneumocystis* pneumonia and is indicated in those with CD40L and CD40 deficiency. Regular monitoring of GI manifestations and management of neutropenia is mandatory. Neutropenia should be treated with a trial of granulocyte macrophage–colony-stimulating factor (GM-CSF), since some have responded to this therapy. Bone marrow transplantation is a viable option for patients that fail to respond to supportive therapy.

SELECTIVE IGA DEFICIENCY

Selective IgA deficiency (IgAD), selective IgG subclass deficiencies, CVID, and a syndrome of recurrent sinopulmonary infections (RESPIs) with normal serum Ig levels appear to share an overlapping set of gene defects.[22] Clinically, these disorders are marked by an increased susceptibility to upper and lower respiratory infections with encapsulated bacteria. IgAD and CVID feature similar B-cell differentiation arrests but differ in the extent of Ig deficits. The correlation between serum Ig levels and severity of infection is not absolute.[23]

Diagnosis

Approximately 1 in 600 individuals of European ancestry are unable to produce detectable quantities of IgA1 and IgA2, making selective IgAD the most frequently recognized primary immunodeficiency in the Americas, Australia, and Europe. The diagnosis is dependent on the sensitivity of the laboratory measurement. The clinical laboratory typically reports serum IgA levels of less than 7 mg/dL, the concentration below which nephelometry becomes unreliable.

Patients with uncomplicated IgAD have normal serum levels of IgM, have normal or elevated levels of IgG, and demonstrate normal cell-mediated immunity. A minority of patients may demonstrate additional evidence of immune dysfunction, with inability to generate appropriate IgG2 anticarbohydrate antibodies, frank IgG subclass deficiencies, or evidence of impairment of T-cell function. Patients with IgA serum levels that fall >2 standard deviations (SDs) below the mean serum level for their age are considered to have partial IgA deficiency. These patients can also suffer from recurrent infections.

Clinical Manifestations

The likelihood that an individual with IgA deficiency that was identified serendipitously will require medical attention is difficult to assess because most studies in the literature reflect patients who were ascertained to have the condition as a result of clinical symptoms. Among patients with IgAD referred to immunology clinics, more than 85% present with recurrent infections, typically with encapsulated bacteria. Among affected children, symptoms may begin in the first year of life, although the physiological lag in serum IgA may delay the diagnosis until after the age of 2 years. In some patients, respiratory infections disappear with maturity. In others, infections may persist throughout adult life. Rarely, patients with IgAD may experience recurrent bronchitis, pneumonia, and even bronchiectasis. These more severely afflicted patients often exhibit concurrent IgG2 and IgG4 subclass deficiencies. Some symptomatic patients have elevated IgE levels and manifest allergic or asthmatic components to respiratory dysfunction. The rise in IgE has been explained as a compensatory response to the absence of IgA. This appears to be a double-edged sword because up to 20% of these patients complain of allergic rhinitis, conjunctivitis, urticaria, and atopic eczema. Allergic reactions may be enhanced because of the lack of IgA-blocking antibodies in serum, and unusually severe asthma has also been associated with IgAD.

Among those less common IgA-deficient patients that are truly devoid of IgA, as many as three-fifths produce IgG or IgE anti-IgA antibodies.[24] These uncommon patients are at an uncertain risk for adverse reactions following transfusion with blood products (as mentioned previously), plasma from normal donors, or from some preparations of Ig replacement therapy, which, of course, contain IgA. Patients with high anti-IgA levels (>1 : 1 000) typically have potent antibodies directed against all IgA. These patients are at risk for severe anaphylaxis. Patients with low anti-IgA antibody titers (<1 : 256) are often multiparous women or those who had received multiple transfusions. These patients rarely demonstrate severe anaphylaxis after infusion with plasma or blood products but do present with hives and rashes.

Patients with IgAD often develop autoimmune diseases. GI disorders include pernicious anemia, inflammatory bowel disease, intestinal disaccharidase deficiency, lactase deficiency, pancreatic insufficiency, and celiac disease. The last, in particular, can be difficult to diagnose without biopsy, since serological diagnosis often relies on detection of antitissue transglutaminase and antiendomysial or antigliaden IgA antibodies.[25] Hepatobiliary disorders include chronic active hepatitis, cholelithiasis, lupoid hepatitis, and primary biliary cirrhosis. Skin disorders include pyoderma gangrenosum, paronychia, and vitiligo. It is unclear whether this autoimmune diathesis is the end result of recurrent infections or is the product of recurrent insult by antigens that would otherwise be cleared by IgA, or whether the underlying deficit that leads to IgAD also increases the risk of developing an autoimmune disorder. For example, autoimmune disorders, such as insulin-dependent diabetes mellitus and celiac disease, are associated with the same major histocompatibility complex (MHC) haplotypes (Chapter 5) as IgAD and CVID.

IgAD is associated with an increased risk for the development of malignant epithelial tumors, such as gastric and colonic adenocarcinoma, Hodgkin disease, and acute lymphoblastic leukemia. Patients with chronic GI infections may demonstrate a nodular lymphoid hyperplasia of the small intestine that can lead to intestinal obstruction. Histological evaluation reveals active B-lymphocyte proliferation in the germinal centers of the Peyer patches. These "constipated" lymph nodes have been mistaken for lymphoma. In others, the simultaneous presence of IgAD and malignancy may simply reflect the high prevalence of IgAD in the Caucasian population.

Origin and Pathogenesis

IgAD, selective IgG subclass deficiencies, and CVID are diseases that are defined by a quantitative phenotype, a paucity of serum Igs of a given isotype in spite of the presence in the blood of B lymphocytes bearing the missing isotypes. By definition, the fundamental defect involves the failure of B lymphocytes bearing a given isotype to differentiate into plasma cells. These diseases appear to represent a common endpoint for multiple pathogenic processes. All three phenotypes may be acquired and many of the recognized precipitating causes, such as phenytoin, are the same (Table 34.3).

TABLE 34.3 Other Conditions Associated With Humoral Immunodeficiency

Genetic Disorders	
Monogenic diseases	Ataxia–telangiectasia Autosomal forms of severe combined immunodeficiency (SCID) Transcobalamin II deficiency and hypogammaglobulinemia Wiskott-Aldrich syndrome X-linked lymphoproliferative disorder (Epstein-Barr virus [EBV] associated) X-linked SCID
Chromosomal anomalies	Chromosome 18q- syndrome Monosomy 22 Trisomy 8 Trisomy 21
Systemic Disorders	
Malignancy	Chronic lymphocytic leukemia Immunodeficiency with thymoma T-cell lymphoma
Metabolic or physical loss	Immunodeficiency caused by hypercatabolism of immunoglobulin Immunodeficiency caused by excessive loss of immunoglobulins and lymphocytes
Environmental Exposures	
Drug-induced	Antimalarial agents Captopril Carbamazepine Glucocorticoids Fenclofenac Gold salts Imatinib Levetiracetam Penicillamine Phenytoin Sulfasalazine Zonisamide
Infectious diseases	Congenital rubella Congenital infection with cytomegalovirus (CMV) Congenital infection with *Toxoplasma gondii* EBV Human immunodeficiency virus (HIV)

IgA deficiency is associated with MHC haplotypes (6p21.3) that are more common in European populations than in the peoples of Sub-Saharan African and East Asia. In the United States, the prevalence of IgAD among African Americans is one-twentieth of that observed among Americans of European descent, and in Japan, the incidence is approximately 1 in 18 500. IgA deficiency has also been observed in family members of patients with CVID with altered function of the transmembrane activator and CAML interactor (TACI, 17p11.2), which is a receptor for B cell–activating factor (BAFF).

Treatment and Prognosis

Most individuals with IgAD suffer respiratory infections no more frequently than the average individual and thus require no special treatment. All individuals with IgA deficiency should be warned of the risk of serious transfusion reactions caused by antibodies to IgA. Wearing a medical alert bracelet is recommended. Should transfusion be necessary, the ideal donors are other individuals with IgAD. Washed erythrocytes are safer than whole blood.

Patients with selective IgA deficiency who suffer from clinically significant, recurrent upper respiratory infections often respond to prophylactic antibiotics with potency against encapsulated bacteria. Treatment of allergy in those patients with a compensatory increase in IgE is helpful. Patients who present with combined IgA and IgG subclass deficiencies and have a poor pneumococcal antibody response may require IG replacement therapy.

COMMON VARIABLE IMMUNODEFICIENCY AND CVID-LIKE DISORDERS

Diagnosis

The diagnostic category of CVID includes a heterogeneous group of patients older than age 4 years and exhibit deficient production of more than one major antibody class and whose antibody response to vaccination is significantly depressed or absent. These patients tend to have normal numbers of clonally diverse B lymphocytes in their blood. These B cells can recognize antigens and respond with proliferation, but their ability to develop into memory B cells or mature plasma cells appears quantitatively impaired. In the presence of infection, abortive differentiation can lead to massive B-lymphocyte hyperplasia, splenomegaly, and intestinal lymphoid hyperplasia.

With an estimated prevalence of 1 in 25 000, CVID is the most prevalent human primary immunodeficiency requiring medical attention.[26] Both sexes are equally affected. As with IgAD, the prevalence among African Americans is one-twentieth that of Americans of European descent. Some patients present during childhood, but most are diagnosed after the third decade of life. The typical patient reports a normal pattern of recurrent otitis media as an infant and toddler that resolved in childhood. During adolescence, respiratory infections appear and steadily increase in frequency and duration. Recurrent pneumonia as a young or middle-aged adult is often the precipitating complaint that brings the patient to the attention of the clinical immunologist. Although CVID appears to be an acquired disorder, family studies have clearly documented that susceptibility for the disease can be inherited and the manifestations of the disorder may change with time. Transitions within the spectrum of normal serum Ig concentrations to IgA deficiency to IgA deficiency with IgG subclass deficits to frank CVID have been documented in both sporadic and familial cases.[2]

CVID is a diagnostic category of primary immunodeficiencies that includes a number of immune disorders. Most patients of Northern European descent with CVID exhibit a distinctive phenotype characterized by a broad deficiency of Ig isotypes in spite of the presence of normal numbers of surface Ig bearing B-cell precursors in peripheral blood. Almost all of these patients are IgA deficient and, by definition, demonstrate total serum IgG levels of <500 mg/dL. Some IgG subclasses are more affected than others, with the sequential order of involvement being IgG4 > IgG2 > IgG1 > IgG3. Most patients are also deficient in IgM and IgE.

Patients with uncomplicated conditions demonstrate normal cell-mediated immunity, although a minority of patients may have evidence of T-cell dysfunction as well as other hematopoietic cell types. In some cases, B-cell numbers are reduced, although not to the extent exhibited by disorders of pre-BCR formation or BTK signaling.

IgAD and CVID have been associated with congenital infection with rubella virus, CMV, and *T. gondii.* The administration of certain drugs has also been linked to a depression in serum Ig levels (see Table 34.1). Several medications used to treat epilepsy have been associated with the development of antibody deficiencies. For example, up to 20% of patients treated with phenytoin develop a mild decrease in serum IgA levels, and a minority may progress to a CVID-like phenotype. Medications used for the treatment of rheumatoid arthritis, inflammatory bowel disease, and chronic myelogenous leukemia can also decrease production of antibody. Persistence of antibody deficiency usually requires choosing between discontinuation of the drug and persisting infection with the virus or parasite. Recovery of Ig production may take months to years.

Clinical Manifestations

Although some patients with CVID have reduced numbers of circulating B cells, the majority has normal quantities of IgA, IgG, and IgM-bearing B-cell precursors in the blood. Defects in B-cell survival, number of circulating $CD27^+$ memory B cells (including IgM^+CD27^+ B cells), B-cell activation after antigen receptor cross-linking, T-cell signaling, and cytokine expression have been observed. Both increases and decreases in the relative numbers of CD4 to CD8 T cells are common, and cutaneous anergy is a frequent finding.

The clinical manifestations of CVID are similar but more severe than the ones seen in IgAD. Respiratory symptoms often begin with recurrent sinusitis, otitis media, and mild bronchitis. The frequency and severity of the upper respiratory infections worsen in the young adult, and lower respiratory infections, such as pneumonia, become common. Apparently asymptomatic, untreated patients may suffer recurrent subclinical pulmonary infections that can lead to irreversible chronic lung damage with bronchiectasis, unilateral hyperlucent lung, emphysema, and cor pulmonale. Recurrent cellulitis, boils, folliculitis, impetigo, or erythroderma can be presenting complaints.

Intermittent or chronic diarrhea due to *G. lamblia* is a common complaint. Patients can develop a malabsorption syndrome that resembles celiac sprue but is unresponsive to gluten avoidance (Fig. 34.4). Untreated patients often complain of asymmetrical, oligoarticular arthralgias or frank arthritis, which in some cases reflect infections with encapsulated organisms or with *Mycoplasma* species and thus require antibiotic therapy. Paradoxically, antigen-specific IgE can be produced in sufficient quantities to enable anaphylactic reactions.

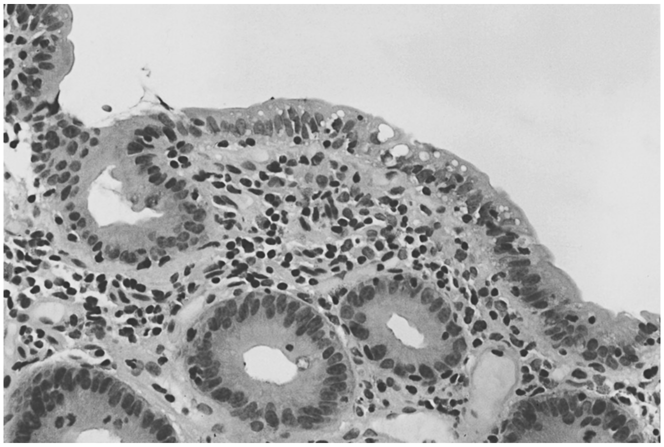

FIG 34.4 Hypogammaglobulinemic Sprue in a 41-Year-Old White Male With Common Variable Immune Deficiency (CVID) and Insulin-Dependent Diabetes Mellitus. The patient suffered from intractable diarrhea. Shown is a hematoxylin and eosin (H&E) stain of a duodenal biopsy obtained by endoscopy. The villi are blunted, and there is a marked increase in intraepithelial lymphocytes. However, unlike typical celiac disease, the villi are not completely blunted, and few plasma cells are seen. The patient is homozygous for the HLA-DQ2, -DR17(3), -B8 haplotype. Although the patient failed to respond to a gluten-free diet, the diarrhea resolved with corticosteroid therapy.

Patients with CVID are often anergic, but only a minority suffers infections characteristic of cell-mediated immune dysfunction, including mycobacteria, *P. jiroveci,* and fungi. CD8 T-cell numbers may be depressed in such patients. Most viral infections are cleared normally. Exceptions include enteroviral infections, including meningoencephalitis, as well as hepatitis B and C, which can progress to chronic active hepatitis. Lack of humoral immunity enhances susceptibility to viral reactivation. Untreated patients often complain of recurrent herpes zoster (shingles).

Autoimmune diseases are common in CVID. Coombs-positive hemolytic anemia with idiopathic thrombocytopenic purpura, a combination known as *Evans syndrome,* may predate the diagnosis of CVID.

Noncaseating granulomas in the lungs, lymph nodes, skin, bone marrow, and liver reminiscent of or indistinguishable from sarcoid-like syndrome is more common in African Americans but can be seen in up to one-fifth of all patients. Occasionally the granulomas result from mycobacterial and fungal infections. In the majority of cases, the cause remains unclear, and the granulomas resolve spontaneously.

There is an increased risk for the development of GI and lymphoid malignancies, especially non-Hodgkin lymphomas. Confounding the diagnosis of malignancy is the patients' propensity to develop benign lymphoproliferative disorders. Lymphadenopathy, splenomegaly, or a combination of both is common in untreated patients.

Origin and Pathogenesis

The typical presenting manifestation of CVID is hypogammaglobulinemia, not agammaglobulinemia, suggesting a partial or varying block in B-cell maturation. Careful analysis of B cells in patients has also revealed a spectrum of immune deficiency ranging from the nearly complete absence of memory B cells to a less severe disorder. All of these findings serve to underline the complex etiology for the disorder, and many details remain to be elucidated. The MHC represents the most common genetic susceptibility locus for CVID.[22] Because of linkage disequilibrium, the gene, or genes, within this locus that create susceptibility have yet to be identified with certainty. Non–MHC-associated single-gene defects have been identified, although they represent only a minority of patients with CVID. These include function-loss mutations in genes involved in late-stage B cell–T cell communication, late-stage B-cell growth factors, and B-cell and T-cell signaling and activation pathways (see Table 34.1). These include the genes for ICOS (CVID1), an immune costimulator molecule used by T cells to activate B cells in germinal centers; BAFFR (CVID4) and TACI (CVID2), the receptors for BAFF, CD19 (CVID3), CD21 (CVID7), and CD81 (CVID6), components of the B-cell costimulatory receptor; CD20 (CVID5), an important marker of B-cell differentiation; and LRBA, Cytotoxic T lymphocyte antigen-4 (CTLA-4), PKCδ, Tweak, PIK3CD, PIK3R1, NF-κB2, and KMT2D, which are involved in B-cell and T-cell signaling pathways. TLR7 and TLR9 activation can be deficient in these patients, although the genes are intact.[27]

The Major Histocompatibility Complex

A large array of genes that play important roles in the control of the immune response are located in the MHC on chromosome 6 (Chapter 5). Studies at the University of Alabama at Birmingham have shown that in the Southeastern United States the majority of patients with IgAD and CVID share parts or all of one of three extended MHC haplotypes marked by either HLA-DQ2, -DR17(3), and -B8 or HLA-DQ2, -DR7, and -B44. The combined results of three studies of patients from Alabama, New England, and Australia indicated a 13% prevalence of immunodeficiency in individuals homozygous for HLA-DQ2, -DR17(3), and -B8. These MHC alleles are also more common in patients who suffer from diabetes mellitus, pernicious anemia, celiac disease, autoimmune thyroid disease, and myasthenia gravis. Some individuals with TACI mutations inherited MHC haplotypes associated with the disease,[28] and the combination of specific MHC and KIR alleles also increases susceptibility.[29] This suggests that epistatic interactions between different susceptibility alleles may influence the penetrance of the disorder.

The CD19 (CVID3), CD81 (CVID6), CD21 (CVID7) B-Cell Coreceptor Complex

CD21 (complement component C3d/Epstein-Barr virus receptor 2) binds to membrane- IgM-bound antigen when complement C3d is also attached to that antigen (Chapter 21). In association with CD81 and CD19, this coreceptor complex enhances the antigen-binding signal, promoting B-cell activation. Patients with mutations in CD19, CD21, and CD81 have been reported.[30]

The BAFF–BAFFR (CVID4)–TACI (CVID2) Axis

The TNF family members B-cell activating factor of the TNF family (BAFF) and a proliferation-inducing ligand (APRIL) bind to two receptors, B-cell maturation antigen (BCMA) and transmembrane activator and calcium-modulator and cyclophilin ligand interactor (TACI), both members of the TNF-R family. BCMA is expressed exclusively on B cells, whereas TACI is expressed on activated T cells as well. A third receptor, BAFF-R, which is unique for BAFF, is expressed on B cells and on resting T cells. The BAFF/APRIL system plays a key role in mature B-cell homeostasis and development. BAFF and APRIL can also induce class switching in naïve human B cells. Loss-of-function (autosomal recessive) or altered-function (autosomal dominant) TACI alleles have been found in approximately 10% of patients with CVID in many series.[31] Two polymorphic alleles, A181E and C104R, are prominent in patients with CVID who have TACI alterations. These alleles are also present in approximately 2% of the normal population, suggesting that the presence of these altered alleles functions as a susceptibility factor for the development of the disease. Family members may have IgA deficiency or may have no evidence of immune dysfunction. However, patients with CVID who have these altered alleles have a higher prevalence of complications from CVID, including lymphoproliferation, splenomegaly, and autoimmune phenomena.[32] BAFF-R deficiency has been reported in four patients with CVID to date.[30]

CD20 (CVID5)

CD20 encodes a B-cell membrane–spanning molecule important in B-cell proliferation and differentiation. It is expressed from early pre-B until mature B-cell stage but is lost on differentiation to plasma cell. One case of a female consanguineous patient with CD20 deficiency with low IgG and normal IgA and IgM levels and impaired antibody responses to pneumococcal polysaccharides, has been reported.[30,33]

ICOS (CVID1)

ICOS is a T-cell surface receptor that is important for germinal center formation, terminal B-cell differentiation, effector T-cell responses, and immune tolerance. Patients with ICOS deficiency have low to absent B cells, and some have varying degrees of defective T-cell signaling. They present with recurrent respiratory tract infections and autoimmune complications.[30,33]

The LRBA (Cvid8)–CTLA-4 Axis

Lipopolysaccharide-responsive beige-like anchor protein (LRBA) is a cytosolic protein that functions in vesicle trafficking, autophagy, and cell survival. It is expressed by almost all cell types with higher expression in immune effector cells. CTLA-4 is an inhibitory T-cell receptor (TCR) that competes with the costimulatory protein CD28 for binding CD80/86, thereby preventing excessive T-cell activation and maintaining immune tolerance. LRBA plays a role in CTLA-4 surface expression.

Patients with LRBA deficiency display early-onset hypogammaglobulinemia with autoimmunity and inflammatory bowel disease. They show reduced levels of at least two Ig isotypes (IgM, IgG, or IgA) and suffer from recurrent infections, autoimmunity, and chronic pulmonary and GI disorders.

Patients with haploinsufficiency of CTLA-4 presented with autoimmunity, recurrent infections, benign lymphoproliferation, and varying levels of Igs and B-cells, and T-cell defects.[30,33]

PKCδ Deficiency

PKCδ plays a key role in BCR-mediated signaling downstream of BTK and is important in B-cell proliferation, apoptosis, and tolerance. PKCδ deficiency presents with a variable phenotype, with one affected patient having a CVID-like characteristics (hypogammaglobulinemia and severe infections) and others having lupus or autoimmune lymphoproliferative syndrome (ALPS)–like disease.[30]

TWEAK Deficiency

A patient with TNF-like weak inducer of apoptosis (TWEAK) deficiency displayed low to normal IgG, low IgM, and low IgA and had a history of pneumococcal meningitis, osteomyelitis, thrombocytopenia, and neutropenia. The patient had an autosomal dominant mutation in TNF superfamily member 12 (*TNFSF12*), which encodes TWEAK.[30]

NF-κB1 (CVID12) and NF-κB2 (CVID10) Deficiency

The NF-κB1 and NF-κB2 (noncanonical) pathways are important in B cell signaling, with NF-κB2 having a more limited set of involved receptors, such as ICOS, TACI, BAFR-R, and BCMA, whereas NF-κB1 affects T-cell and TLR signaling as well.

Heterozygous mutations in NF-κB2 were identified in at least 10 patients who presented with early-onset CVID with autoimmunity and recurrent sinopulmonary infections. Patients with NF-κB2-deficiency display panhypogammaglobulinemia, aberrant B-cell subsets, and some degree of T-cell and NK-cell dysfunction. Half of these also suffer from pituitary hormone deficiencies.

Patients with *NK-KB1* autosomal dominant mutations that create an unstable and rapidly degrading protein have recurrent infections, autoimmunity, benign lymphoproliferative disease, and lymphoma.[30]

PI3K Mutations

Heterozygous mutations in *P1K3CD,* which encodes the P13K catalytic subunit p110δ, have been reported in over 50 patients with CVID-like disease. The mutation leads to P13K signaling pathway overactivity. Such patients suffer from respiratory tract infections, skin infections, autoimmunity, and lymphoma. The phenotype associated with dominant gain of function *P1K3CD* mutations is currently referred to as activated phosphatidylinositol 3-kinase δ syndrome (APDS).

PIK3R1 encodes the P13K regulatory subunit p85α. Splice-site mutation of p85α results in a loss of an exon of p85α, which is important in inhibiting the catalytic activity of p110d. This also results in autosomal dominant overactive P13K signaling. A single patient with a homozygous *P1K3R1* mutation causing complete loss of p85α expression has been found with agammaglobulinemia and absence of B cells, suggesting complete absence of p85α reduces inhibiting P13K signaling.[30]

Other Genes: *BLK, IRF2BP2, IKAROS*

A heterozygous loss of function mutation in *BLK* has been noted in related patients with CVID. These patients have respiratory tract infections and bacterial skin infection with panhypogammaglobulinemia.

A gain of function mutation in *IRF2BP2* has been found in members of a family with CVID. These patients have autoimmune disease and respiratory tract infections.

Heterozygous mutation in the gene *IKZF1,* encoding the transcription factor IKAROS, was recently found in patients with CVID and low B-cell numbers. These patients have progressive loss of B cells and serum Igs.[30]

Kabuki Syndrome

Kabuki syndrome (KS) is a rare but recognizable condition that consists of a characteristic face, short stature, cardiac anomalies, a variable degree of intellectual disability, and immunological defects. Mutations in *KMT2D* and *KDM6A* have been identified as the main cause for KS. Similar to CVID, patients with KS have recurrent infections, reduced Ig levels, and autoimmunity.[34]

Treatment and Prognosis

Therapy in CVID begins with the aggressive treatment of ongoing infections and the institution of prophylactic measures to prevent or ameliorate future infections. Patients suffering from moderate upper respiratory tract infections and bronchitis will likely benefit from empiric therapy with agents effective against encapsulated organisms. The concomitant inheritance of MBL protein deficiency appears to further predispose to the development of bronchopulmonary complications, such as bronchiectasis, lung fibrosis, and respiratory insufficiency.[3] The course of treatment for patients with immunodeficiency is often prolonged, and intravenous administration of antibiotics may be required.

The most effective therapy for hypogammaglobulinemia is Ig replacement. A number of studies have demonstrated a steadily decreasing incidence of infection with increasing frequency of Ig administration. At higher doses, even patients with bronchiectasis may experience improvement in pulmonary function. Each patient may demonstrate his or her own individual response to therapy, exhibiting dramatic differences in the frequency and severity of infections, with moderate changes in the replacement dose. Patients suffering from a serious acute infection often benefit from one-time booster doses of Ig. Ultimately, replacement dosage must be individualized based on the response of the patient. Adverse reactions occur most frequently at the time of the first administration of Ig, likely because of concurrent infection increasing the potential for generation of immune complexes.

Some patients with CVID can sustain severe anaphylaxis when given IVIG or other blood products that contain serum or plasma. These patients may possess anti-IgA antibodies, including IgE anti-A antibodies.[7] For patients with a history of severe adverse reactions, it is advisable to try batches of IVIG with the lowest IgA possible and to test the patient with the different batches in an intensive care unit. Once the clinician has identified a batch that can be tolerated, the patient may receive therapy under more relaxed conditions.

Serum Ig concentrations in patients with CVID may change over time,[2] with rare patients regaining normal serum IgG levels and no longer requiring Ig therapy. Careful review of the clinical history of these patients may reveal evidence of exposure to pharmacological agents associated with the development of hypogammaglobulinemia (*e.g.,* phenytoin). However, the overwhelming majority of patients require replacement therapy for life.

Although IgG can be replaced, at present IgM and IgA cannot be provided to patients. The absence of these multimeric proteins may help explain why even patients on high-dose replacement therapy may continue to suffer from recurrent sinusitis or GI discomfort.[35] Recurrent sinusitis can be ameliorated with continued prophylactic therapy with antibiotics. Patients with CVID also are at risk of infection by *G. lamblia* as well as other enteric pathogens. Some patients develop lactose intolerance or gluten-sensitive enteropathy. Gluten avoidance ameliorates symptoms in only a minority of cases. A majority responds to corticosteroids or anti-TNF agents. The use of these agents can be a double-edged sword, however, since resistance to infection will decrease in a patient who already has immune deficiency. Other patients develop a malabsorption syndrome that can lead to hypoalbuminemia and hypocalcemia (as a result of malabsorption of vitamin D), and decreased levels of vitamin A and carotene.[36] The cause of diarrhea and malabsorption in this latter patient subset remains unclear, and treatment is limited to supportive measures, with vitamin and mineral replacement as indicated.

Patients with bronchiectasis should be treated aggressively with replacement therapy. In severe cases, aggressive pulmonary toilet will benefit the patient, including bronchodilator therapy, position and postural drainage, or other physical therapies. The use of corticosteroids should be avoided.

Mothers with IgA deficiency may fail to secrete IgA in their colostrum. Although colostral IgM levels may be elevated in an attempt to compensate for the lack of maternal IgA, the newborn remains relatively unprotected against intestinal pathogens. Of greater concern is the fact that the babies of mothers with untreated CVID are born in a state of humoral immunodeficiency and thus are at risk for life-threatening sinopulmonary infection. To compensate for the loss of IgG across the placenta and to provide the infant with the passive immunity that will be required, the dose of replacement gammaglobulin therapy should be increased by 50% during the third trimester of pregnancy.

Splenomegaly is common in untreated patients. Hypersplenism in most patients responds to aggressive therapy with antibiotics and IVIG. The presumption is that the hypersplenism is secondary to reactive hyperplasia of lymphoid follicles within the spleen attempting to respond to infection. Development of esophageal varices or other hematological manifestations of hypersplenism (refractory thrombocytopenia, anemia, neutropenia, and lymphopenia) may require splenectomy as the therapy of last resort. The outcome for most such patients has been good, with resolution of symptoms, although patients with altered TACI alleles tend to do less well.

The development of a constellation of pulmonary abnormalities that include granulomatous and lymphoproliferative histopathologic patterns (lymphocytic interstitial pneumonia [LIP], follicular bronchiolitis, and lymphoid hyperplasia), termed granulomatous–lymphocytic interstitial lung disease (GLILD), can be an ominous sign. These patients appear more likely to develop granulomatous liver disease, autoimmune hemolytic anemia, lymphoproliferative disease, and progressive pulmonary disease.[37]

THERAPEUTIC PRINCIPLES

- The primary goal of treatment is to keep the patient infection free.
- In patients whose respiratory mucosa is intact, intravenous or subcutaneous replacement immunoglobulin G (IgG) therapy is generally effective in protecting the patient from pulmonary infections.
- For those patients who have developed bronchiectasis or who continue to subject themselves to environmental toxins (*e.g.,* smoking), replacement IgG will ameliorate but may not prevent all such infections.
- Because mucosal Ig cannot be replaced, even patients on adequate IgG replacement therapy remain at risk for sinus or gastrointestinal infections.
- Prophylactic antibiotics that are effective against encapsulated organisms can significantly reduce the frequency of upper respiratory tract infections in patients who continue to suffer in spite of replacement therapy with intravenous immunoglobulin (IVIG).
- Prolonged diarrhea in patients with hypogammaglobulinemia is often caused by *Giardia lamblia* and responds well to metronidazole therapy.
- Patients with primary antibody deficiencies should not receive live vaccines.

SELECTIVE IGG SUBCLASS DEFICIENCIES

Diagnosis

A diagnosis of clinical immunodeficiency should be supported by clear evidence of functional impairment. Most individuals with modest reductions in serum IgG subclass levels are functionally normal. Indeed, individuals with deletions of the heavy chain Ig gene locus, some of whom completely lack IgG1, IgG2, IgG4, and IgA[38] have been reported to be asymptomatic.

The diagnosis of a functional IgG subclass deficiency can thus be made with confidence only when there is both a significant decrease in the serum concentration of a specific isotype and there is clear evidence of abnormal specific antibody production. Up to 10% of normal males and 1% of normal females have IgG4 deficiency, which makes a diagnosis of immunodeficiency as a result of an isolated IgG4 subclass deficiency problematic. Among patients with a deficiency of IgG1 or IgG3, documentation of the ability to produce protective titers of antitetanus toxin and antidiphtheria toxin antibodies following standard tetanus toxoid and diphtheria immunizations is a strong indication that replacement gammaglobulin therapy is likely unwarranted. Similarly, documentation of a strong antipneumococcal polysaccharide response in patients with an apparent IgG2 deficiency would suggest gammaglobulin replacement is likely not required. IgG2 levels normally begin to rise in childhood later than other subclasses. Conversely, the lack of a response to vaccination calls for appropriate prophylactic antibiotic therapy before a trial of IVIG is attempted.

Clinical Manifestations

The clinical spectrum of isolated IgG subclass deficiency is quite variable, and deficiencies of each of the four IgG subclasses have been described. Some individuals are referred to the clinical immunologist with only a mild reduction of total IgG, but most symptomatic patients have marked deficiencies of one or more IgG subclass despite normal total IgG concentrations. Since IgG1 makes up the majority of serum IgG in most patients, a deficiency of IgG1 tends to correlate with depressed serum levels of total IgG.

Determination of IgG subclasses is rarely performed on asymptomatic individuals; thus most patients with an isolated IgG2 deficiency come to medical attention as a result of recurrent sinusitis, otitis media, or pulmonary infections. Individuals may have few residual symptoms between infections, but some have severe chronic inflammation with refractory sinusitis, pulmonary fibrosis, or bronchiectasis. Because protective antibodies directed against carbohydrate antigens are usually of the IgG2 subclass, many affected patients exhibit an impairment of their ability to mount specific protective responses to encapsulated pathogens. However, normal responses have also been described.[39] Many clinicians would agree, however, that patients with IgG2 deficiency, who suffer from recurrent sinopulmonary infections and who respond to less than half of the polysaccharide antigens with which they have been challenged, meet the standard for functional immune deficiency and thus warrant aggressive prophylactic therapy up to and including Ig replacement should the infections be severe.

IgG3 deficiency can occur alone or in association with IgG1 deficiency. Recurrent infection of the respiratory tract with chronic lung disease has been reported. With a serum half-life only 2 weeks, IgG3 levels may be consumed rapidly during the course of an active infection in an otherwise normal individual.[40]

Before making the diagnosis of IgG3 deficiency, serum levels of IgG3 should be rechecked when the individual is asymptomatic.

Compared with the serum, IgG4 is overrepresented in secretions, and IgG4-committed B cells are present at mucosal sites, suggesting a role in mucosal immunity. Since IgG4 is normally present in the serum in very low concentrations, the significance of a low serum level in a patient with recurrent infection remains unclear.

Origin and Pathogenesis

The origin of IgG subclass deficiency is unknown. Homozygous deletions of portions of the Ig heavy chain constant locus associated with total absence of IgG2, IgG3, and IgG4 or combinations of these isotypes have been described in healthy individuals. IgG2 deficiency is often found in association with selective IgA deficiency with or without IgG4 deficiency, and patients with selective IgG subclass deficiencies have been shown to have inherited the same MHC haplotypes as those who suffer from IgAD and CVID. These observations suggest that patients with recurrent infections have a more complex defect than the mere elimination of one or more IgG isotype. In some instances, subclass deficiency is associated with a T-cell defect, as in chronic mucocutaneous candidiasis and ataxia–telangiectasia. IgG subclass deficiency can be acquired. Acute infections, medications, chemotherapy, irradiation, surgery, and human immunodeficiency virus (HIV) infection have all been temporally linked to the development of a deficiency in one or more IgG subclass.[41]

Treatment and Prognosis

The natural history of IgG subclass deficiency plus or minus IgA deficiency, especially in children, is not constant.[42] Associated allergic rhinosinusitis and asthma must be aggressively treated with conventional therapy for these disorders, as these conditions increase the risk of purulent sinusitis and pneumonia. Causes of anatomical obstruction should be sought when persistent infection of a sinus or pulmonary segment is the presenting complaint; the role of surgical therapy for anatomical obstruction should not be overlooked.

Many patients with IgG subclass deficiency do well on prophylactic antibiotics and will never need Ig supplementation. However, Ig replacement therapy can be beneficial in patients with severe, recurrent infections. Patients who begin therapy should improve within the first 2 months, but to avoid the placebo effect, a full 6-month trial is recommended.

ANTIBODY DEFICIENCY WITH NORMAL SERUM IMMUNOGLOBULIN LEVELS

Occasional patients may present with normal serum Ig concentrations and a selective inability to respond to infections with pyogenic organisms. Diagnosis requires documentation of an inability to respond to antigenic challenge. These patients may respond to replacement Ig therapy. The antibody response to specific polysaccharide antigens can be very selective. In human, most protective anti-*H. influenzae* type b (anti-Hib) antibodies utilize the rare *VκA2* gene. The Navajo population in the Southwestern United States suffers a 5- to 10-fold increased incidence of Hib disease. This population also exhibits a high prevalence of an A2 allele with a defective recombination signal sequence, preventing use of germline-encoded antibodies that can generate protective antigen-binding sites.[43]

Analysis of a group of well-characterized patients, mostly female, with a history of RESPIs and normal serum Ig levels revealed a high prevalence of the same MHC haplotypes observed in IgAD, selective IgG subclass deficits, and CVID.[23] These patients tend to respond to aggressive antibiotic therapy, including prophylaxis.

SELECTIVE LIGHT-CHAIN DEFICIENCY

Selective deficiencies of either κ or λ light chains have been reported.[44-46] In one such case, the patient was the offspring of a consanguineous (uncle–niece) union; and in the second, a molecular analysis demonstrated different loss of function mutations in the patient's Cκ alleles. The parents of these children had no health difficulties, but each of the patients required medical attention for recurrent sinopulmonary infections and diarrhea. Two of the patients with κ deficiency exhibited IgA deficiency, and the remaining patients with κκ deficiency and λ deficiency had panhypogammaglobulinemia.

TRANSIENT HYPOGAMMAGLOBULINEMIA OF INFANCY

Diagnosis

As infants make the transition from dependence on maternal Ig to reliance on endogenously produced antibodies, they suffer a physiological nadir of serum Ig at 4–6 months of age, a period associated with susceptibility to mild upper respiratory infections and otitis media (see Fig. 34.2). Children who *(i)* exhibit serum concentrations of one or more of the three major Ig classes that fall below the 95% confidence interval (CI) for age on ≥2 occasions during infancy, *(ii)* demonstrate a rise in these values to or toward normal over time, and *(iii)* lack features consistent with other forms of primary immunodeficiency fall within the catch-all diagnosis of transient hypogammaglobulinemia of infancy (THI).[47,48] By definition, the diagnosis of THI can be made with certainty only in retrospect.

Clinical Manifestations

Ig concentrations are rarely measured in infants unless there is some reason to suspect an immunodeficiency. Most patients with this diagnosis come to medical attention because of either recurrent infections or as a result of routine screening studies of relatives of other patients with immunodeficiency. Yet bearing in mind that 2.5% of normal infants will fall below the 95% CI range at any one time, the diagnosis of THI is remarkably rare. Among two major centers, one in the United States and one in Germany, the diagnosis was given to only 16 of 18 000 children in whom the index of suspicion warranted Ig determinations.[49,50]

Patients with THI typically are able to synthesize specific antibodies in response to immunization with T-dependent antigens (*e.g.,* tetanus and diphtheria toxoids).[51] They may have difficulty, however, responding to polysaccharide antigens (*e.g.,* isohemagglutinins and vaccination with Pneumovax23). Some will fail to sustain protective antibody responses to antigens. Most patients with THI, especially those ascertained as a result of family studies or mild upper respiratory infections alone, exhibit fewer infections over time. The great majority of infants with THI will normalize their serum Ig levels within 24 months of age. However, a minority fails to normalize IgG, continues to suffer with recurrent infections, and may develop evidence of autoimmune disease. These patients often become part of the hypogammaglobulinemia syndrome complex that includes CVID and may ultimately require long-term therapy with gammaglobulin, prophylactic antibiotics, or both.

Treatment and Prognosis

Children with suspected THI should be monitored with serial determination of serum Igs and isohemagglutinin titers to confirm acquisition of normal immune function. Some children will not achieve normal levels of IgG for several years, and some will remain IgG subclass or IgA deficient. Treatment of THI with IVIG is generally not warranted unless the child suffers from persistent, recurrent, invasive infections, including pneumonia.

ON THE HORIZON

- Elucidation of the molecular basis of selective defects in humoral responses to pathogens, in part through the use of high-throughput sequencing to characterize the precise molecular composition of antibody responses in immune deficiencies
- Further elucidation of the molecular basis of common variable immune deficiency, hypogammaglobulinemia, and immunoglobulin A (IgA) deficiency

FRONTIERS IN RESEARCH

Bruton reported the first case of agammaglobulinemia in 1952, as well as the first successful therapy for this classic primary antibody deficiency. There has been remarkable progress in the identification of single-gene disorders since that time. However, for the majority of patients the underlying pathogenesis of the most common manifestation of primary antibody deficiency in our population, that is, hypogammaglobulinemia in the adult, still remains unclear. It seems increasingly likely that this disorder is multifactorial in nature, dependent on the inheritance of one or more susceptibility loci in association with either environmental influences or random chance. In rare cases, patients with hypogammaglobulinemia have shown resolution of their symptoms, suggesting that a better understanding of pathogenesis might yield therapies of remission. The molecular basis of selective deficiencies in the response to pathogens in the presence of normal serum Ig levels also remains unclear. The availability of whole exome sequencing and whole-genome sequencing has helped identify the genetic cause of an increasing number of patients with presumed CVID. More genes and likely presumptive alleles will be found in the next decade.

MULTIPLE-CHOICE QUESTIONS

1. A 50-year-old man presents with a history of two pneumonias in the last 2 years. He has suffered occasionally with sinusitis and bronchitis since childhood, but these infections have readily responded to antibiotic therapy, and he denies dyspnea on exertion. A grandson is receiving therapy for an unknown immune deficiency. Serum immunoglobulin (Ig) levels are drawn. IgM is <20 g/dL. IgG is 100 mg/dL. IgA is <7 mg/dL. Flow cytometry reveals rare B cells. He has no response to pneumococcal polysaccharide vaccination. What is the most likely diagnosis?
   - **A.** Hyper-IgM syndrome
   - **B.** Common variable immune deficiency
   - **C.** X-linked agammaglobulinemia
   - **D.** Autosomal agammaglobulinemia

2. A 35-year-old woman presents with a 10-year history of recurrent sinopulmonary infections. She has suffered with allergic rhinitis since childhood and was diagnosed with celiac disease at age 15 years. Serum immunoglobulin (Ig) levels are drawn. IgM is 100 g/dL. IgG is 650 mg/dL. IgA is <7 mg/dL. Flow cytometry reveals normal B-cell numbers. After vaccination with Pneumovax23, she responds to only five of 23 pneumococcal polysaccharide antigens. She has never smoked, and testing for cystic fibrosis is negative. She complains of dyspnea on climbing more than one flight of stairs and suffers with fatigue. She suffered pneumonia once as a child. What would be the best approach?
   - **A.** The patient has selective IgA deficiency. She should be treated with antibiotics, as needed, for infections.
   - **B.** The patient may have an IgG subclass deficiency in addition to IgA deficiency. She should be treated with prophylactic antibiotics, since gammaglobulin replacement is contraindicated for patients with IgA deficiency.
   - **C.** The patient may have an IgG subclass deficiency in addition to IgA deficiency. She should be treated with gammaglobulin replacement therapy.

3. A 2-month-old baby girl presents with her second episode of bacterial pneumonia. Serum immunoglobulin (Ig) levels are drawn. IgM is 100 g/dL. IgG is 100 mg/dL. IgA is <7 mg/dL. Flow cytometry reveals normal B-cell numbers. What is the most likely diagnosis?
   - **A.** Selective IgA deficiency
   - **B.** Transient hypogammaglobulinemia of infancy
   - **C.** Common variable immune deficiency
   - **D.** Maternal common variable immune deficiency

Primary T-Cell Immunodeficiencies

Chaim M. Roifman

This chapter is dedicated to the diagnosis and management of inherited immune defects associated predominantly with T-cell dysfunction. One of the central roles of T cells is the coordination of both the humoral and cell-mediated arms of the immune system; therefore T-cell deficiencies are often accompanied by dysfunction of other cell types, such as B and natural killer (NK) cells. The focus of this chapter is on primary immunodeficiencies that are profound enough to require hematopoietic stem cell transplantation (HSCT) or other modalities of management and treatment directed at T-cell absence or dysfunction.

T-CELL IMMUNODEFICIENCIES

KEY CONCEPTS

T-Cell Immunodeficiency

- A group of disorders are caused by defects in genes critical to the growth, maturation, and survival of T lymphocytes.
- Some defects may also affect other arms of the immune system, such as B cells, natural killer (NK) cells, or components of innate immunity.
- The immune defects may be one feature of a multisystem syndrome.
- The age of presentation and diagnosis varies widely from early infancy (or at birth when detected through newborn screening) to adulthood.
- The spectrum of clinical manifestations is wide and encompasses presentation at early infancy with extreme susceptibility to opportunistic infections (severe combined immunodeficiency [SCID]) or disorders featuring predominately autoimmunity or predisposition to cancer (combined immunodeficiency [CID]).

SEVERE COMBINED IMMUNODEFICIENCY

KEY CONCEPTS

Severe Combined Immunodeficiency

- Infants present typically at 4–6 months of age with severe persistent infections, oral thrush, chronic diarrhea, and failure to thrive. Siblings of affected patients and cases detected through newborn screening are diagnosed before symptoms occur.
- By definition, affected infants have a permanent profound T-cell lymphopenia of <300–500 CD3 cells/μL, with or without reduced numbers of circulating B cells and natural killer (NK) cells.
- Invariably, *in vitro* responses to T-cell mitogens are depressed and T-cell receptor excision circle (TREC) levels are low or undetectable.
- Ideally, patients with severe combined immunodeficiency (SCID) should be placed in protective isolation and offered hematopoietic stem cell transplantation (HSCT) (or, in some cases, gene therapy).

The most clinically severe and studied group of patients are those traditionally designated as having severe combined immunodeficiency (SCID). The clinical hallmarks of SCID include consistent clinical presentation in the first year of life, with repeated life-threatening bacterial, viral, or fungal infections, chronic diarrhea, and failure to thrive.[1] Evaluation of the immune system typically reveals profound T-cell lymphopenia of <500 CD3 cells,[2,3] or according to more stringent definitions, <300 T cells. Invariably, *in vitro* responses to mitogens are severely depressed and T-cell receptor excision circle (TREC) numbers are markedly reduced or below detection.[4] The identification of these cases by TREC-based newborn screening (NBS) is the earliest alert of T-cell deficiency.[5]

COMBINED IMMUNODEFICIENCY

The second large group of disorders with significant T-cell deficiency is loosely designated as combined immunodeficiency, which is arbitrarily defined by the presence of >300–500 autologous CD3 cells/μL in the circulation.[3,4] The omission of "severe" from this category of patients might be misleading, as many of these patients present with signs and symptoms indistinguishable from SCID. This category of heterogeneous deficiencies can be further subdivided into subgroups that are discussed in detail in this chapter. They include T-cell deficiencies that invariably or frequently present with normal or close to normal numbers of circulating lymphocytes, such as zeta-associated protein-70 (ZAP-70) deficiency. Other disorders are caused by hypomorphic mutations in genes associated with SCID[3] and are therefore frequently referred to as "leaky SCIDs." A third subgroup encompasses patients with multisystem syndromes that include variable degrees of T-cell deficiency, such as cartilage hair hypoplasia and DiGeorge syndrome. Finally, a fourth group involves more selective T-cell defects, such as FOXP3 deficiency, which predispose patients to a limited array of infections or are associated with autoimmunity or lymphoid malignancies. There may be a wide range of clinical manifestations, from typical SCID presentation to mild or delayed presentation. Laboratory features are also extremely variable but universally reflect T-cell dysfunction.[6,7]

OMENN SYNDROME

Omenn syndrome (T^+B^+ SCID; OMIM #603554) is an aberrant inflammatory process associated with "leaky SCID" phenotypes, which characteristically allow for thymic escape and propagation of poorly controlled T-cell clones.[8] T-cell development is severely

KEY CONCEPTS

Combined Immunodeficiency

- Arbitrarily defined as a T-cell deficiency with >300–500 autologous CD3 circulating cells/µL, which may be reduced or dysfunctional.
- Circulating autologous T cells may be the typical feature of the defect or may be caused by genetic variants leading to an incomplete defect (leaky severe combined immunodeficiency [SCID]).
- Clinical manifestations may be indistinguishable from SCID.
- Others may present with SCID and aberrant inflammatory syndrome (Omenn syndrome) consisting of erythroderma, lymphadenopathy, and eosinophilia.
- Frequently, the predominant presenting manifestation can be autoimmunity or lymphoid malignancy.
- *In vitro* responses to mitogens and T-cell receptor excision circle (TREC) levels may be depressed or normal. The T-cell repertoire is often abnormal, as are T-cell subpopulations (regulatory T cells [Tregs] and memory cells). Immunoglobulins and specific antibodies are variable.

restricted because of inefficient deletion and suppression of self-reactive T cells and dysregulated lymphostromal cross-talk in the thymus. The condition is associated with hypomorphic mutations of various SCID-causing genes, including *RAG1/2, Artemis, DNA ligase IV, RMRP, ZAP-70, IL2RG, IL7Rα, CD3δ,* and *ADA* (Table 35.1). In addition to typical SCID manifestations, patients present with features including generalized erythroderma, which may be accompanied by alopecia, loss of eyebrows and eyelashes. Marked enlargement of lymph nodes, liver, and spleen are frequently present.

The hallmarks of laboratory findings are elevated serum immunoglobulin E (IgE) levels and increased eosinophil counts. T-cell number may be normal or even elevated, but the T-cell repertoire is skewed with overrepresentation of a few T-cell clones and underexpression or absence of most other Vβ families[9] (Chapter 8). Skin biopsy reveals acanthosis and parakeratosis. Dyskeratosis and spongiosis are seen in the Malpighian layer, and vacuolization is often observed in the basal layer. The thymus is dysplastic, and expression of the transcription factor autoimmune regulator (AIRE) in medullary thymic epithelial cells is reduced.[10]

TABLE 35.1 T-Cell Immunodeficiency With Autologous T Cells Associated With Omenn Syndrome

Gene Defect	Immune Phenotype	Additional Features
RAG1	$T^+B^-NK^+$	None
RAG2	$T^+B^-NK^+$	None

DNA ligase IV	$T^+B^-NK^+$	Irradiation sensitivity, microcephaly
Adenosine deaminase	$T^+B^{-/+}NK^{-/+}$	Multisystem involvement
ZAP-70	$T^+B^+NK^+$	None
RMRP	$T^+B^+NK^-$	Short stature, metaphyseal dysplasia
γc (IL-2Rγ)	$T^+B^+NK^-$	None
IL-7Rα	$T^+B^+NK^+$	None
22q11.2 microdeletion	$T^+B^+NK^+$	DiGeorge syndrome
CD3δ	$T^+B^+NK^+$	None

T^+ = >500 CD3 cells/µL

Regardless of the molecular cause, treatment with corticosteroids and cyclosporine are effective in controlling inflammation, improving skin lesions, and reducing lymphadenopathy and hepatosplenomegaly. Ultimately, a cure can be achieved only with HSCT.[11]

SEVERE COMBINED IMMUNE DEFICIENCY

SCID is characterized by near complete absence of circulating autologous T cells and impaired B-cell function. Defects in the differentiation and maturation of T-lineage cells in the thymus are a primary cause of T-cell deficiency (Fig. 35.1). In particular, mutations affecting T-cell activation or downstream signaling molecules can result in SCID or CID (Fig. 35.2).

SCID With T-Cell Lymphopenia (T^-B^+)

This T^-B^+ group of patients (Table 35.2) is the most frequently identified phenotype of SCID (28 to 50% of all cases) and is believed to occur at a frequency of 1:50,000 live births.[1]

γc (IL-2Rγ) Deficiency

Common gamma chain (γc) or interleukin-2 receptor gamma (IL-2Rγ) deficiency (OMIM #300400) is transmitted in an X-linked manner. Affected males have mutations in the IL-2Rγ chain, also known as the *common gamma chain* because of its critical role as a coreceptor in IL-4, IL-7, IL-9, IL-15, and IL-21 receptors. Multiple pathways downstream of these receptors are essential for differentiation and growth of T cells and NK cells, hence the abnormal immune profile and profound defect in T-cell and NK-cell maturation. Affected males typically present at 3–6 months of age, with failure to thrive and repeated microbial and fungal infections. Infections are fatal unless HSCT is administered.

Evaluation of the immune system typically reveals extremely low to absent T and NK cells, while sparing B cells ($T^-B^+NK^-$). *In vitro* responses to mitogens are profoundly depressed, TRECs are undetectable, and the thymus appears dysplastic with absence of Hassall corpuscles and disrupted architecture.

γc deficiency may have an atypical presentation because of hypomorphic mutations. Various degrees of autologous T-cell or NK-cell levels have been reported. Importantly, patients with the R222C mutation can present with SCID-like symptoms but have normal numbers of T cells and NK cells, near normal responses to mitogens, normal TREC levels, and structurally normal thymus gland.[12] Cure can be achieved by providing HSCT. Gene therapy has recently been attempted but remains an experimental procedure.

JAK3 Deficiency

Janus kinase-3 (JAK3) deficiency (OMIM #600802) is an inherited autosomal recessive mutation mimicking the presentation of γc deficiency. This is expected, as JAK3, a lymphoid specific tyrosine kinase, is a signaling molecule downstream of the γc receptor. Upon IL-2 binding, JAK3 phosphorylates signal transducer and activator of transcription (STAT) factors, which dimerize and translocate to the nucleus, where they bind regulatory elements, thus inducing target genes.

Patients typically present with SCID features, but similar to γc, patients with JAK3 deficiency may also present with combined immunodeficiencies and autologous T cells. Milder phenotypes of T-cell deficiency caused by hypomorphic mutations in JAK3 have also been described. Some patients have been diagnosed during

FIG 35.1 **Impaired Maturation of T-Lineage Cells in the Thymus Can Lead to Profound T-Cell Deficiency.** Lymphoid progenitor cells originating from bone marrow reach the thymus and mature into functional T cells. During differentiation, naïve thymocytes (DN, double-negative cells) undergo β chain rearrangement and pairing of the β chain with the pre-Tα chain, giving rise to cells expressing both CD4 and CD8 (DP, double-positive cells). After positive and negative selection, thymocytes downregulate the expression of either CD4 or CD8, resulting in single-positive cells. These cells emigrate from the thymus to blood and secondary lymphatic organs, where they encounter antigens and exert their biological functions. Various defects in this process can cause profound T-cell deficiencies. Blocked lines indicate specific stages impaired by known genetic abnormalities. Some defects may also interfere with maturation of B and natural killer (NK) cells. late childhood (age 6 years), with some remaining asymptomatic. Additionally, patients may present with lymphoproliferative disorder, whereas others remain asymptomatic, despite carrying the same mutation.

IL-7Rα Deficiency

IL-7 receptor α (IL-7Rα) deficiency is transmitted in an autosomal recessive manner and is caused by mutations in the IL-7Rα chain. Together, IL-7Rα chain and γc forms the IL-7R (OMIM*146661), which is essential for the normal development of T cells. This receptor mediates survival and proliferative signals to thymocytes during the early stages of cell maturation. Patients carrying such mutations present in early infancy with typical features of SCID. Even mutations that preserve the production and expression of the faulty IL-7Rα chain result in a SCID phenotype. Immune evaluation reveals the absence of circulating T cells but preserved B and NK cells ($T^-B^+NK^+$). Cure can be attained with HSCT.

CD45 Deficiency

CD45 deficiency(OMIM*151460) is an extremely rare autosomal recessive form of SCID. CD45 is a receptor tyrosine phosphatase that regulates Src tyrosine kinases involved in T-cell receptor (TCR) and B-cell receptor (BCR) signaling. In the absence of functional CD45, thymocytes are prevented from transitioning from $CD4^+CD8^+$ double-positive cells to single-positive $CD4^+$ or $CD8^+$ expressing mature T cells. Patients present with a SCID phenotype and assessment of immunity shows low to absent T cells but normal numbers of B and NK cells ($T^-B^+NK^+$). Interestingly, while $TCR\alpha\beta^+$ T cells are absent, $TCR\gamma\delta^+$ cells are preserved.

FOXN1 deficiency ($T^-B^+NK^+$)	AR	Impaired maturation of thymus and epithelial cells	Alopecia; nail dystrophy	HSCT, thymus transplantation

CD3–TCR Complex Defects

Biallelic mutations in the CD3δ (OMIM *186790), ε (OMIM *186830), and ζ (OMIM *186780) coreceptor chains can result in a typical SCID phenotype ($T^-B^+NK^+$). Together with CD3γ (OMIM *186740), these transmembrane proteins function as signaling molecules for the antigen recognizing TCR heterodimer, which is composed of either the αβ or γδ chains. CD3δ deficiency leads to a complete absence of both the αβ and γδ TCR on circulating CD3 cells because of blockade in thymocyte development at the CD4, CD8 double-negative to double-positive stage. The thymus appears normal in size but lacks Hassall corpuscles. Complete deficiencies (null mutations) in CD3ε and CD3ζ also result in a lack of circulating T cells. Atypical presentations are associated with leaky defects of CD3ε or CD3δ. Although clinical presentation could be indistinguishable from typical SCID, these patients may have a sizeable amount of autologous T cells ($T^+B^+NK^+$). Cure of CD3 deficiencies can be achieved with HSCT.[13]

SCID With T-Cell Lymphopenia and Syndromic Features

Coronin-1A Deficiency

Coronin-1A (OMIM *605000) is a leukocyte-specific signaling molecule, which is essential for TCR ligation–dependent generation of inositol-1,4,5-triphosphate (IP3). IP3 mediates Ca^{2+} release from intracellular stores and is critical for the proper function of downstream signaling enzymes, culminating in T-cell activation and survival. In addition, coronin-1A is essential for lymphocyte migration and lymphocyte homeostasis.

Patients with coronin-1A deficiency (OMIM #615401), an autosomal recessive condition, can present during infancy with a SCID phenotype ($T^-B^+NK^+$), including oral thrush, recurrent respiratory infections, BCG lymphadenitis, or Epstein-Barr virus (EBV)–associated lymphoproliferation. Others may present at a much older age (11 years) with EBV-associated lymphoproliferation and a $T^+B^+NK^+$ CID presentation. Evaluation of the immune system reveals a very low number of circulating T cells, absent naïve T cells, abnormal T cell repertoire and markedly reduced TREC levels. In-vitro responses to mitogens are variably reduced. Serum immunoglobulin levels are within normal range but production of specific antibodies in response to vaccination is impaired. Imaging can detect a thymus shadow. The associated syndromic features consist of developmental delay, growth retardation, low cognitive functions, and attention deficit disorder. Immune function can be restored with HSCT.

FOXN1 Deficiency (Combined Immunodeficiency With Alopecia Totalis)

Forkhead box protein N1 (FOXN1) deficiency (OMIM #601705) is an autosomal recessive syndrome encompassing alopecia, which affects the scalp, eyebrows, and eyelashes; nail dystrophy, which is noted at birth; and profound cellular immunodeficiency. The syndrome is caused by mutations in the *FOXN1* gene, a member of the forkhead/winged helix transcription factor family, which is mainly expressed in the thymus epithelium and in skin. *FOXN1* plays a critical role in the maturation of the thymus and skin epithelial cells. A deleterious mutation in this gene was identified in nude athymic mice. Patients can present at 2–4 months with Omenn syndrome, recurrent infections, and failure to thrive. Circulating lymphocytes may be low or normal with CD4 lymphopenia, and yet the TCR repertoire is restricted. Circulating T cells are phenotypically immature and double $CD4^-CD8^-$. While TRECs are low, *in vitro* responses to mitogens are variable. Both HSCT and thymus transplantation have been tried in these patients. HSCT led to full engraftment and infection-free clinical recovery. However, immune reconstitution and maturation of donor stem cells are still in question. Thymus transplantation appears successful, with recovery to lymphocyte repertoire and function.

SCID With T-Cell and B-Cell Lymphopenia (T^-B^-)

Up to 30% of all SCID cases appear to lack both circulating T cells as well as B cells (Table 35.3).

RAG1/2 Deficiency

This type of SCID (OMIM #601457) has an autosomal recessive pattern of inheritance and is caused by mutations in the recombination activating genes *RAG1* (OMIM *179615) and *RAG2* (OMIM *179616). Recognition of different antigens is mediated

TABLE 35.3 Severe Combined Immunodeficiency (SCID) With T- and B-Cell Lymphopenia (T^-B^-)

Disease (Immune Phenotype)	Inheritance	Molecular Defect/Presumed Pathogenesis	Additional Features	Treatment
RAG1/2 deficiency ($T^-B^-NK^+$)	AR	Defective V(D)J recombination	None	Hematopoietic stem cell transplantation (HSCT)
Artemis deficiency ($T^-B^-NK^+$)	AR	Defective V(D)J recombination, radiation sensitivity; DCLRE1C gene defects	None	HSCT
DNA-PK deficiency ($T^-B^-NK^+$)	AR	Defective V(D)J recombination	None	HSCT
DNA Ligase IV deficiency ($T^-B^-NK^+$)	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay; microcephaly; bone marrow abnormalities; lymphoid malignancies	HSCT
Cernunnos deficiency ($T^-B^-NK^+$)	AR	Defective V(D)J recombination, radiation sensitivity	Growth delay; microcephaly; bird-like facies; bone defects	HSCT
AK2 deficiency/reticular dysgenesis ($T^-B^-NK^-$)	AR	Impaired mitochondrial energy metabolism and leukocyte differentiation	Deafness	gCSG HSCT
Adenosine deaminase deficiency ($T^-B^-NK^-$)	AR	Accumulation of toxic purine nucleosides	Neurological, hepatic, renal, lung, skeletal and bone marrow abnormalities	HSCT, PEG-ADA, gene therapy

by antigen-specific TCR or BCR. This requires the production of variable regions of the antigen receptors, a process known as *V(D)J recombination* (Chapter 4). Proper recognition of BCR and TCR are important for maturation of these lineages as well as clonal expansion. RAG1 and RAG2 are the chief enzymes responsible for recombination of the antigen receptors. Patients who carry null mutations present with typical SCID features at infancy; however, hypomorphic mutations can be associated with Omenn syndrome. Other leaky phenotypes have been reported with moderate lymphopenia and autoimmunity; EBV-associated lymphoproliferation or noninfectious granulomas of the skin, bones, lymphoid tissues, and the respiratory system; and CD4 lymphocytopenia.

Diagnosis is supported by flow cytometry showing marked reduction in circulating T and B cells in null mutations or by profoundly skewed T-cell repertoire in hypomorphic cases. Autologous cells fail to respond to mitogens or antigens and TREC levels are low. Immunoglobulins (Igs) and specific antibodies are lacking.[4] Cure can be achieved by administering HSCT, even in cases of Omenn syndrome.[11] Gene correction is currently being investigated as an alternative option to HSCT.[14]

Artemis Deficiency

Artemis deficiency is an autosomal recessive disorder caused by mutations in the DNA cross-link repair 1C (*DCLRE1C*) gene (OMIM *605988), encoding the protein Artemis. Similar to RAG1/2, *DCLRE1C* is obligatory for DNA recombination of antigen receptors, by opening RAG-generated coding hairpins in a DNA protein kinase-dependent manner. Artemis is critical for the repair of genomic lesions and is essential for genomic stability. Clinically, patients may present with typical SCID features. Hypomorphic mutations in the Artemis gene may present with Omenn syndrome, and EBV-associated lymphoma has also been reported. HSCT remains the sole modality for curing this condition. Because of the genomic instability caused by Artemis deficiency, these patients may be sensitive to ionizing radiation and possibly chemotherapy, and therefore reduced intensity conditioning is advised.

KEY CONCEPTS

Diagnosis of T-Cell Immunodeficiencies

- T-cell receptor excision circle (TREC)–based newborn screening detects all types of profoundly lymphopenic T-cell severe combined immunodeficiency (SCID) and may detect some, but not all, cases of combined immunodeficiency (CID).
- Immunophenotyping remains an indispensable tool in the diagnosis of all types of T-cell immunodeficiencies. When needed, expanding the panel of markers to detect regulatory T cells (Tregs) as well as naïve and memory T cells and B cells can be valuable.
- Genetic analysis has become the gold standard for diagnosis of T-cell immunodeficiency. Modern next-generation sequencing allows for analysis of SCID or CID panels. Whole exome sequencing enables identification of both known as well as novel defects in the immune system.
- Basic functional assays, such as responses to mitogens, are still widely used to aid in the diagnosis of SCID and CID. Analysis of cytokine secretion, cytokine autoantibodies, and detailed study of T-cell receptor repertoire all contribute to better defining immunodeficiency. Novel mutations should be assessed by studying their impact on protein translation and function.
- Thymus biopsies can be helpful when considering high-risk procedures, such as hematopoietic stem cell transplantation (HSCT). Although normal thymus morphology cannot exclude primary T-cell deficiency, abnormal thymus architecture and abnormal Hassall corpuscles are specific and sensitive predictors of primary T-cell deficiency. This invasive procedure should be restricted to cases where all other diagnostic tools remain inconclusive, and a life-saving procedure is considered. It should only be performed in centers with abundant experience with this procedure.

SCID With T-Cell and B-Cell Lymphopenia (T^-B^-) and Syndromic Features

DNA-PKcs Deficiency

DNA-dependent protein kinase, catalytic subunit (DNA-PKcs) deficiency is caused by mutations in the *PRKDC* gene (OMIM *600899) and is transmitted in an autosomal recessive manner.

The serine/threonine kinase recognizes open DNA ends and is part of a complex involved in the nonhomologous end joining (NHEJ) pathway essential for DNA recombination. Clinical presentation is indistinguishable from SCID, with virtually absent T cells and B cells but normal NK cells. These patients may present with severe neurological abnormalities.[15] HSCT may be a curative option, although caution must be exercised during the conditioning regimen because of the underlying defect in DNA repair.

DNA Ligase IV Deficiency

DNA ligase IV deficiency (OMIM #606593) is clinically pleomorphic with presentations ranging from intact immunity to a SCID phenotype. Other features include facial dysmorphia, various degrees of developmental delay, and microcephaly. These features are consistent with DNA ligase IV knock-out mice, which are characterized by defective lymphogenesis and neurogenesis. DNA ligase IV is a component of the NHEJ complex and participates in the repair of DNA double-strand breaks that arise during DNA damage, such as from ionizing radiation, or the endogenous recombination process. Hypomorphic mutations in DNA ligase IV can be associated with increased sensitivity to radiotherapy,[16] EBV-associated lymphoproliferation and T-cell leukemia. Diagnosis may be challenging, with immune evaluation revealing low to absent T cells and B cells during infancy in some patients, whereas in others diagnosis may be delayed to the second decade of life in individuals with various degrees of lymphopenia and hypogammaglobulinemia. Microcephaly and developmental delay can help in the diagnosis if present. HSCT was attempted in patients with DNA ligase IV deficiency with limited success because of increased toxicity of conditioning regimens as well as graft-versus-host disease (GvHD).

Cernunnos Deficiency

Patients with Cernunnos deficiency (OMIM #611291) present early in life with profound T-cell lymphopenia, progressive decrease in B cells (T^-B^- SCID), and microcephaly. The syndrome has an autosomal recessive pattern of inheritance. Cernunnos (OMIM *611290) forms a complex with DNA ligase II and XRCC4 and likely plays an important role in the NHEJ pathway. Disruption of Cernunnos, like other members of this pathway, is associated with radiosensitivity. Clinical presentation consists of recurrent infections, as in typical SCID, as well as developmental delay, microcephaly, urogenital and bone malformations, and facial dysmorphic features.

AK2 Deficiency (Reticular Dysgenesis)

Adenylate kinase-2 (AK2) deficiency, also known as *reticular dysgenesis* (OMIM #267500), is a profound inherited immune deficiency characterized by severe lymphopenia and marrow failure. The disorder has an autosomal recessive pattern of inheritance and is caused by mutations in the *AK2* gene.[17,18] Mitochondrial AK2 catalyzes the reversible phosphorylation between nucleoside triphosphates and monophosphates. AK2 defects are associated with impaired mitochondrial energy metabolism and leukocyte differentiation. Patients suffer repeated bacterial, viral, and fungal infections and have bilateral sensorineural deafness.[17] Patients present in infancy with profound neutropenia and lymphopenia, the thymus is dystrophic, and TRECs are undetectable. Diagnosis is confirmed by genetic analysis. Bone marrow reconstitution can be achieved with HSCT and remains the most effective modality of treatment.

Adenosine Deaminase Deficiency

Adenosine deaminase (ADA) deficiency (OMIM #102700) is an autosomal metabolic disorder caused by deleterious mutations in the *ADA* gene (OMIM*608958). This is a critical enzyme that aids in the degradation and salvage of purine pathway metabolites and is essential for multiple processes, such as energy transfer and DNA metabolism. Damage to various tissues and lesions in the immune system are caused by toxic accumulation of undegraded metabolites, such as deoxyadenosine. Thymocytes are particularly sensitive, but B cells and NK cells are also frequently affected. Because toxicity to lymphocytes is lineage specific and time dependent, patients may present with T^-B^- or T^-B^+ phenotype. Some may have Omenn syndrome and present with T^+B^- or T^+B^+.[19] Mutations that spare some ADA activity may result in a delayed presentation.[20] Patients with ADA deficiency mostly present with typical SCID features or Omenn syndrome, while patients with "partial deficiencies" can present with CID, autoimmunity, and susceptibility to malignancy.[21] Other associated features include brain anomalies resulting in various levels of developmental delay and bone, liver, lung, and kidney anomalies. Standard diagnostic tools for this disorder demonstrate barely detectable ADA enzyme activity and increased accumulation of purine metabolites in blood or urine. The diagnosis can be confirmed by genetic analysis. Polyethylene glycol-conjugated ADA (PEG-ADA) can be used for "detoxification"; however, salvage of complete or even partial immunity may not be achieved, and efficacy may be short lived.[22] HSCT remains the treatment of choice if a full human leukocyte antigen (HLA)–matched related donor is available. For other patients, gene therapy is gradually becoming standard of care.[23]

COMBINED IMMUNODEFICIENCY (SCID PHENOTYPE)

Combined immunodeficiencies presenting with features typical of SCID are summarized in Table 35.4.

ZAP-70 Deficiency

ZAP-70 deficiency (OMIM #269840) is a rare CID with an autosomal recessive pattern of inheritance. The disease was first described as a novel immunodeficiency with normal numbers of circulating CD4 cells but CD8 lymphopenia. ZAP-70 is a protein tyrosine kinase critical in mediating T-cell receptor signaling. Upon phosphorylation and activation, ZAP-70 phosphorylates a host of downstream molecules culminating in T-cell proliferation and maturation.[24] Patients typically present within the first 2 years of life with repeated severe microbial infections indistinguishable from SCID. However, unlike typical SCID, patients with ZAP-70 deficiency also present with palpable lymph nodes, visible tonsils, and a normal thymus shadow on imaging. Rarely, patients present with autoimmune manifestations, Omenn syndrome, hemophagocytic lymphohistiocytosis (HLH), subcutaneous nodules, or lymphoma.[25,26]

Immune evaluation reveals normal numbers of circulating lymphocytes but marked reduction in CD8 cells.[4,7] Responses to mitogens are depressed; however, the T-cell repertoire of CD4 cells appears normal. The thymus gland is fully developed with normal architecture and normal corticomedullary distinction, including the presence of Hassall corpuscles. However, the corticomedullary ratio appears increased. B-cell number and Ig

TABLE 35.4 Combined Immunodeficiency (Severe Combined Immunodeficiency [SCID] Phenotype)

Disease	Inheritance	Molecular Defect/Presumed Pathogenesis	Features	Treatment
ZAP-70 deficiency	AR	Abnormal T-cell receptor signaling	Normal thymus size; increased corticomedullary ratio	Hematopoietic stem cell transplantation (HSCT)
Major histocompatibility complex (MHC) class II deficiency	AR	Absence of human leukocyte antigen (HLA) class II molecules	Recurrent infections; gastrointestinal manifestations; hepatic abnormalities	Supportive
MHC class I deficiency	AR	Impaired expression of HLA class I molecules	Respiratory infections; skin granulomatous lesions	Supportive
DOCK2 deficiency	AR	Impaired T-cell homing	Viral and bacterial infections	HSCT
CD3γ deficiency	AR	Arrest of thymocyte differentiation at the CD4$^-$CD8$^-$ stage	Thymus size may be normal	HSCT
CARD 11 / BCL10 / MALT1	AR	Abnormal signaling upstream of NF-κB pathway	Opportunistic infections	HSCT
TTC7A deficiency	AR	*TTC7A* gene defects; impaired regulation of transcription, cell cycle, protein degradation and trafficking	Intestinal atresia	HSCT
ORAI-1, STIM-1		Impaired Ca^{2+} fluxes	Autoimmunity; ectodermal dysplasia	HSCT

levels are normal. NK cells may be reduced in some patients (personal communication). Allogeneic HSCT can completely correct the immunodeficiency.

MHC Class II Deficiency (Bare Lymphocyte Syndrome)

MHC class II deficiency is a rare immunodeficiency characterized by the lack of expression of HLA class II molecules (OMIM #209920). The deficiency is caused by mutations in genes encoding transactivating elements critical for regulating HLA class II expression. Such deleterious disease causing mutations have been identified in the class II transactivator (CTIIA), the regulatory factor–associated protein (RFXANK or RFX-B), the fifth member of the regulatory factor X family (RFX5) and the regulatory factor–associated protein (RFXAP).

HLA class II is expressed on thymic epithelial cells, antigen-presenting cells (APCs), and activated lymphocytes. The structure and function of these molecules, which are required for T-cell maturation and antigen presentation, are discussed in detail in Chapters 5 and 6.

Clinical manifestations are highly variable with some patients presenting with features of typical SCID, including oral thrush, *Pneumocystis jiroveci* pneumonia, and failure to thrive. Others may have a milder course. Chronic enterocolitis and sclerosing cholangitis are common and are caused by infections. Meningoencephalitis caused by enteroviruses, herpes simplex, or adenoviruses has also been reported. Autoimmune cytopenias are common.

Historically, the diagnosis relied on demonstrating the lack of MHC class II expression on APCs by flow cytometry. Lymphocyte counts are usually normal, but CD4 lymphocytopenia is frequently observed. *In vitro* responses to mitogens may be normal or depressed, but TREC levels are within normal limits. The definitive diagnosis is made by mutational analysis. Overall, the prognosis for patients with this condition is poor. Patients usually die within the first or second decade of life, as a result of infections or infection-related organ damage. HSCT is offered, but outcomes are usually poor, with a high rate of engraftment failures, severe GvHD, and poor immune reconstitution. Supportive treatment consists of antibiotics and Ig replacement.

MHC Class I Deficiency

This is a rare autosomal recessive immune deficiency characterized by partial expression of HLA class I molecules (OMIM #604571). The decrease in HLA class I expression is caused by mutations in *TAP1* (OMIM *170260) or *TAP2* (OMIM *170261). These endoplasmic adenosine triphosphate (ATP)–binding transporters are essential for processing the association of endogenous peptides with MHC class I molecules. MHC class I molecules that do not bind high affinity peptides do not cross the Golgi apparatus. Recently mutations in the genes encoding tapasin and β_2 microglobulin, involved in antigen and HLA class I molecule processing, have been shown to result in a similar deficiency. Patients present during childhood or later in life with lung infections and/or skin granulomatous lesions. The diagnosis is suspected when HLA class I expression is decreased upon immunophenotyping. Confirmation of the diagnosis is obtained by genetic analysis. Treatment remains supportive in nature.

DOCK2 Deficiency

Dedicator of cytokinesis 2 (DOCK2) deficiency (OMIM #616433) is an autosomal recessive combined immunodeficiency. DOCK2 (OMIM *603122) mediates cytoskeletal reorganization through Rac activation and is required for lymphocyte homing to lymphoid tissues. Indeed, DOCK2-deficient mice exhibit lymphocyte migration defects.

Patients with DOCK2 deficiency experience severe invasive bacterial and viral infections at early childhood. Patients may have T-cell lymphopenia and reduced *in vitro* T-cell proliferation, reduced circulating B cells, defective NK-cell activity, and antibody deficiency.[27] Although experience is very limited, HSCT may cure this condition.

CD3γ Deficiency

CD3γ deficiency (OMIM #615607) is caused by mutations in the CD3γ chain and is transmitted in an autosomal recessive manner. Patients can present with a SCID phenotype or with delayed atypical features, consisting of infections or autoimmunity. This unusual heterogeneous clinical pattern has been observed in patients of Turkish or Spanish descent. Autologous T cells have partial TCR/CD3 expression with only mild lymphocytopenia ($T^+B^+NK^+$). *In vitro* responses of mitogens are depressed, and TRECs can be reduced. Although some of these patients present as typical SCIDs or with severe colitis, other family members with an identical mutation appear well, even into adulthood.

CARD11/BCL10/MALT1 (CBM) Complex Deficiencies

CARD11/BCL10/MALT1 deficiencies are autosomal recessive immunodeficiencies caused by mutations in signaling molecules upstream of the NF-κB pathway. Upon TCR or BCR stimulation, caspase recruitment domain family, member 11 (CARD11) is phosphorylated, enabling its association with BCL10–MALT1 complex, to form the CBM complex. The CBM complex allows for activation of the NEMO–IκB kinase (IKK) complex, which induces phosphorylation of IκB and causes its breakdown. As a consequence, NF-κB is released and translocates into the nucleus, where it acts as a transcription factor, controlling multiple cellular processes, such as cell proliferation, differentiation, and survival.

Patients with CARD11 deficiency (OMIM #615206) may present with a SCID phenotype.[28] They also suffer gingivitis and aphthous ulcers. Patients with MALT1 deficiency (OMIM #615468) present at a later age during childhood with severe enterocolitis and recurrent lung infections.[29] Evaluation of the immune system in CARD11 deficiency shows normal number of circulating T cells, B cells, and NK cells, but regulatory T cells (Tregs) are absent (T^+B^+ SCID). Responses to mitogens are reduced but not absent, and TRECs and the TCR repertoire are normal. B cells appear immature, which explains the panhypogammaglobulinemia found in these patients. Patients with MALT1 deficiency present similarly; however, although Ig levels are normal, antibody production is faulty. Cure can be achieved with HSCT.

Autosomal dominant CARD11 deficiency is caused by a dominant negative monoallelic mutation and results in combined immunodeficiency, severe atropy and autoimmunity.

COMBINED IMMUNODEFICIENCY (SCID PHENOTYPE) AND SYNDROMIC FEATURES

TTC7A Deficiency (MIA Syndrome)

TTC7A deficiency is a rare autosomal recessive disorder in which obstructions occur at various levels of the gut, hence the designation *multiple intestinal atresia* (MIA) syndrome (OMIM #243150).[30] Patients may also have severe lung disease and pulmonary calcifications. Immune deficiency is commonly associated with this syndrome and is frequently severe. Patients may present with typical SCID features,[31] albeit with various levels of autologous T cells. The disease is caused by mutations in the *TTC7A* gene (OMIM *609332), which encodes a protein containing nine tetratricopeptide repeat (TPR) domains. These domains are degenerate 34-amino acid repeat motifs and appear to play a role in multiple cellular processes, such as transcription, cell cycle, protein degradation, and trafficking.

Evaluation of the immune system in TTC7A deficiency reveals T-cell lymphopenia and markedly depressed responses to mitogens. The TCR repertoire is restricted, and TRECs are low. The thymus appears dysplastic with poor corticomedullary demarcation, as well as poorly developed Hassall corpuscles. Nonimmune manifestations are striking, with intraluminal calcifications. In some patients, atresias cannot be detected; rather, severe colitis with characteristic features of mucosal atrophy and massive enterocyte apoptosis is present.[32] The prognosis of this condition is poor. Although HSCT can replenish the hematopoietic system,[30] this does not solve the complex and fatal gastrointestinal (GI) manifestations. Combined gut and bone marrow transplantation could be attempted.

Calcium Channel Defects (ORAI-1, STIM-1 Deficiencies)

This is an autosomal recessive disorder caused by mutations in ORAI-1 (OMIM *610277) and STIM-1 (OMIM *605921).[33] ORAI-1 is a transmembrane protein, which at tetramer configuration constitutes the pore-forming structure of a Ca^{2+} channel. STIM-1 is a calcium sensor of the endoplasmic reticulum (ER) and controls calcium entry after ER store depletion. Both Ca^{2+} influx into the cell as well as release from cytosolic stores are mediated through the TCR and BCR, and are critical for downstream signaling. Patients may present in infancy with recurrent severe infections indistinguishable from SCID.[34] Patients with STIM1 deficiency can also present with autoimmune features, such as arthritis and cytopenia, as well as lymphoproliferative manifestations. Both deficiencies may present with severe eczema and syndromic features, including nail dysplasia and anhydrosis, ectodermal dysplasia, and generalized myopathy. Immune evaluation shows normal to elevated lymphocyte counts and TREC levels, and responses to mitogens are depressed. Ig levels are normal, but specific antibodies are variable. TCR-mediated cytosolic rise in Ca^{2+} is low. HSCT can be effective in reversing the immunodeficiency, but not the syndromic features.

COMBINED IMMUNODEFICIENCIES WITH VARIABLE SEVERITY (NON-SCID)

Combined Immunodeficiency With Immune Dysregulation

Combined immunodeficiencies characterized by autoimmune manifestations are summarized in Table 35.5.

IL-2Rα (CD25) Deficiency

IL-2 receptor α (IL-2Rα or CD25) deficiency is a complex immune dysregulation disorder that has an autosomal recessive pattern of inheritance (OMIM #606367). Biallelic mutations in the CD25 gene result in combined immunodeficiency ($T^+B^+NK^+$). The high affinity IL-2 receptor must be composed of all three components, the γ chain (γc), β chain (CD122), and α chain (CD25), to be functional. Although the β and γ chains are constitutively expressed on T cells, expression of the α chain is limited to early thymocytes, Tregs and activated T cells. The inability to form the high affinity receptor results in faulty T-cell differentiation, loss of central and peripheral tolerance, and failure to respond appropriately to infections. Affected infants present with recurrent infections, lymphadenopathy and hepatosplenomegaly, a variety of autoimmune features, and eczematous skin lesions. Patients may present immediately after birth with diabetes mellitus and may suffer severe chronic lung disease or pulmonary bleeding. Autoimmune lymphocytic infiltrates can be identified in multiple tissues, including lung, liver, gut, and bone. Autoimmune disorders include primary cirrhosis, colitis, thyroiditis, or insulin-dependent diabetes mellitus.

Evaluation of the immune system reveals reduced numbers of circulating T cells, which are unable to respond to mitogens or antigens, but normal B cells. The thymus appears dysplastic with absent Hassall corpuscles and loss of corticomedullary demarcations. Thymocytes do not express CD1 and fail to downregulate

TABLE 35.5 Combined Immunodeficiency With Immune Dysregulation

Disease	Inheritance	Molecular Defect/Presumed Pathogenesis	Features	Treatment
Interleukin (IL)-2Rα / CD25 deficiency	AR	Impaired T-cell differentiation	Recurrent infections; autoimmunity	Hematopoietic stem cell transplantation (HSCT)
FOXP3 deficiency	X-linked	Impaired regulatory T cell (Treg) development	Autoimmunity; impaired barrier function in skin and gut; enteropathy	HSCT
IL-10, IL-10R deficiency	AR	Impaired antiinflammatory cytokine production	Early onset inflammatory bowel disease (IBD); autoimmunity	HSCT
IKK2 deficiency	AR	Disruption of NF-κB pathway	Recurrent fungal and viral infections; failure to thrive	HSCT
DOCK8 deficiency	AR	Disruption in cell adhesion and migration	Recurrent infections; atopy; early onset malignancy; autoimmunity	HSCT
RHOH deficiency	AR	Defective Rho guanosine triphosphatase (GTPase) expression resulting in impaired T-cell receptor (TCR) signaling	Human papilloma virus (HPV) infections	HSCT
MAGT1 / CTPS1 / SH2DIA / BIRC 4	X-linked, AR	Variable depending on associated defect	Epstein-Barr virus (EBV) lymphoproliferation	HSCT
PNP deficiency	AR	Abnormal purine metabolism	Recurrent infections; autoimmunity, neurological abnormalities	HSCT
DiGeorge syndrome	AD	Deletion in chromosome 22q11.2 resulting in impaired TBX1 transcription factor, affecting developmental processes	Omenn syndrome; Truncus arteriosus; autoimmunity; cardiac defects; hypocalcemia; dysmorphism; cleft palate; short stature; neuropsychiatric problems	Supportive
Wiskott-Aldrich syndrome	X-linked recessive	Impaired actin cytoskeleton rearrangement and immunological synapse formation	Eczema; autoimmunity; malignancy	HSCT
Ataxia telangiectasia	AR	Impaired DNA repair and cell cycle regulation	Cerebellar ataxia; telangiectasias; predisposition to malignancy; radiosensitivity	Supportive
Nijmegen breakage syndrome	AR	Impaired DNA repair and cell cycle regulation	Microcephaly; growth retardation; predisposition to malignancy; radiosensitivity	Supportive

levels of the antiapoptotic protein Bcl-2. This results in marked reduction of apoptosis and the expansion of autoreactive clones in multiple tissues. The markedly reduced Tregs in the absence of CD25 explains the uncontrolled expansion of these clones, resulting in autoimmunity. HSCT cures this disorder.

FOXP3 Deficiency

Mutations in the Forkhead box protein P3 (*FOXP3*) gene cause an X-linked recessive disorder, also known as IPEX (immune dysregulation/polyendocrinopathy/enteropathy/X-linked) syndrome (OMIM #304790). The protein encoded by FOXP3, termed *scurfin,* is a transcription factor that plays a critical role in the development and function of $CD4^{+}CD25^{+}$ Tregs (Chapter 18). Affected patients suffer from severe autoimmunity in infancy. Severe enterocolitis is often the presenting feature. Insulin-dependent diabetes mellitus, hepatitis, autoimmune cytopenias, and arthritis are frequent. Patients may also have increased frequency of invasive bacterial infections. Circulating lymphocytes are present in normal numbers, and they respond normally to mitogen stimulation. TREC levels are also normal. However, the number and function of $CD4^{+}CD25^{+}FOXP3^{+}$ Tregs is reduced. Patients have normal Ig and antibody levels, as well as increased autoantibodies against various tissues. Immunosuppressive drugs can transiently control the autoimmune phenomena, but HSCT offers the best option for cure, particularly if performed early before irreversible organ damage occurs.[35]

IL-10 and IL-10Rα and IL-10Rβ Deficiencies

IL-10, produced mainly by T cells and macrophages, is a key antiinflammatory cytokine. Biallelic deleterious mutations in IL-10 (OMIM *124092) or its receptor IL-10R, composed of α (OMIM *146933) and β (OMIM *123889) chains, causes early-onset severe inflammatory bowel disease (OMIM #613148, #612567).[36] Patients suffer perianal abscesses and fistulas that often require surgical intervention. Some patients with IL-10/IL-10R deficiency also develop other autoimmune manifestations, such as rheumatoid arthritis. Treatment with immunosuppressive agents may provide partial and temporary remission. Only HSCT proved effective in completely reversing colitis. However, other autoimmune features, such as arthritis, may persist.

IKK2 Deficiency

IKK2 deficiency (OMIM #615592) is a combined immunodeficiency that is inherited in an autosomal recessive manner and is caused by biallelic mutations in the *IKBKB* gene (OMIM *603258), leading to disruption of the nuclear factor-κB (NF-κB) pathway. The NF-κB pathway regulates immune responses, cell activation and growth, as well as cell survival.[34] The canonical pathway encompasses the NF-κB essential modulator (IKKγ, or NEMO), IKK1 (IKKα), and IKK2 (IKKβ). Upon activation of the complex, IKK2 phosphorylates inhibitors of NF-κB, which are degraded, therefore allowing nuclear translocation of NF-κB and DNA binding. Patients present with oral thrush, pulmonary infections, and invasive bacterial infections.[38] Evaluation of the immune system reveals normal numbers of circulating T cells but reduced NK cells. Responses to mitogens are variable, TREC levels are normal, and the TCR repertoire is intact. The B-cell compartment lacks memory B cells ($T^+B^+NK^-$).[38] HSCT is a plausible choice for treatment; however, results so far are very limited and variable. Like other NK-κB pathway disorders, engraftment may be incomplete using current bone marrow transplantation protocols.

DOCK8 Deficiency

Dedicator of cytokinesis 8 (DOCK8) deficiency (OMIM #243700) is an autosomal recessive combined immunodeficiency combined with severe atopy.[39] DOCK8 interacts with Rho guanosine triphosphatases (GTPases) and is believed to be involved in cytoskeletal rearrangement, affecting cell adhesion and motility. Patients suffer recurrent respiratory infections and, less frequently, invasive bacterial and fungal infections. In addition to severe eczema, patients may have extensive warts and molluscum contagiosum. Food allergies, asthma, and anaphylaxis have also been documented. Immunological assessment shows great variability with variable number of T cells and B cells but increased eosinophil counts. Responses to mitogens appear normal. IgG is elevated, but other serum Ig levels and specific antibodies are variable.[39] Treatment is dictated by the various atopic and infectious manifestations.

RHOH Deficiency

This is an autosomal recessive immunodeficiency caused by mutations in the Ras homologue gene family member H gene (RHOH; OMIM *602037), which is mostly expressed in the hematopoietic system. Upon ligation of TCR, RhoH undergoes phosphorylation on tyrosine residues and leads the recruitment of Zap-70 and Lck to downstream signaling pathways. Patients may present with persistent skin infections, granulomatous lung disease, and Burkitt lymphoma. Circulating lymphocytes, Igs, and antibody production are all normal, and *in vitro* responses to mitogens are variable.[40]

COMBINED IMMUNODEFICIENCY WITH EBV-INDUCED LYMPHOPROLIFERATION

EBV-induced chronic infection and lymphoproliferation is the major clinical presentation of a growing number of newly described inherited immunodeficiencies. Inheritance can be X-linked or autosomal recessive according to the gene affected. Hemizygous mutations in the magnesium transporter 1 (*MAGT1*) gene (OMIM *300715) causes reduced TCR-mediated Mg^{2+} as well as Ca^{2+} influx into T cells (OMIM #300853). This ultimately results in abnormal downstream activity of transcription factors. Patient CD4 T cells are reduced, but the total numbers of CD3 cells, B cells, and NK-cells are normal. EBV related infections or lymphoma may develop at any age.[41] A similar clinical picture (OMIM #615897) is found in patients with biallelic CTP synthase 1 (CTPS1; OMIM *123860) mutations.[42] The nucleotide cytidine-5'-triphosphate (CTP) is needed for the metabolism of RNA and DNA. Circulating lymphocyte counts are variable, Ig levels are normal, and responses to mitogens are normal in most patients. Some patients suffer bacterial infections as well as chronic EBV viremia, and HSCT has been sometimes successful.[42]

EBV-induced lymphoid proliferation and lymphoma (OMIM #613011) can also be caused by biallelic mutations in the IL-2 inducible T-cell kinase (*ITK*) gene.[43] X-linked lymphoproliferative syndrome-1 (XLP, OMIM #308240) and -2 (XLP2, OMIM #300635) are caused by hemizygous mutations in *SH2DIA* (XLP1) and *BIRC4* (XIAP), respectively.[44] Patients can present with overwhelming EBV infection causing liver necrosis and failure, aplastic anemia, or with chronic EBV infections culminating in malignant lymphoma. Some patients present with hypogammaglobulinemia and antibody deficiency, and some others may develop hemophagocytic lymphohistiocytosis.[45] XLP2 is more frequently associated with chronic colitis.[46] Lymphocyte numbers and response to mitogens are typically normal, whereas NK-cell activity may be impaired. HSCT can reverse the susceptibility to EBV.[45]

COMBINED IMMUNODEFICIENCY WITH IMMUNE DYSREGULATION AND SYNDROMIC FEATURES

PNP Deficiency

Purine nucleoside phosphorylase (PNP) deficiency (OMIM # 613179) is an autosomal recessive multisystem syndrome caused by mutations in PNP, a key enzyme in the purine salvage pathway. PNP catalyzes the phosphorylation of guanosine, deoxyguanosine, inosine, and deoxyinosine. This pathway is responsible for balancing the production of dephosphorylated purines and degradation to uric acid and salvage back to the nucleotide level. Lymphotoxicity is caused by accumulation of dGTP in mitochondria inducing apoptosis, and T-cell toxicity may be related to the need for high deoxyguanosine phosphorylation activity in T cells. Indeed, PNP-deficient mice created by gene targeting have no detected PNP activity and demonstrate a sharp reduction in T-cell numbers and function due to loss of double positive $CD4^+CD8^+$ progenitors, as well as progressive loss of peripheral T cells.

Patients with PNP deficiency display similar abnormalities in T-cell maturation and function.[4] The thymus appears partially dysplastic. Circulating T-cell numbers are reduced, and T-cell function is depressed. Igs and specific antibody levels may be variable. B- and NK-cell numbers are variable. Patients with PNP deficiency typically present with a triad of features, including recurrent infections, autoimmune manifestations, and various neurological abnormalities. Infections may be consistent with SCID, but severe bacterial infections have been mostly reported in older patients with delayed presentation. Autoimmune features include cytopenias, systemic lupus erythematosus (SLE), and arthritis, and neurological features consist of ataxia and various degrees of behavioral and mental retardation. Diagnosis is confirmed by demonstrating markedly reduced PNP enzyme activity in red blood cells (RBCs) or T cells, reduced uric acid, an increase of deoxyguanosine and other metabolites in blood and urine, and by genetic analysis of the *PNP* gene. HSCT may reverse the immunodeficiency, but not the neurological manifestations.

DiGeorge Syndrome

DiGeorge syndrome (DGS; OMIM #188400) comprises thymic hypoplasia, parathyroid hypoplasia, and outflow tract malformations of the heart. The syndrome is caused by a 1.8–3.0 Mb hemizygous deletion in chromosome 22q11.2. Haploinsufficiency of the *TBX1* gene (OMIM *602054), which is localized within the deleted region, can be solely responsible for this disorder. Less frequently, DGS can be caused by defects in other chromosomes, notably 10p13. DGS is one form of several phenotypically overlapping disorders, including conotruncal anomaly and velocardiofacial syndrome. Clinically, patients may present with neonatal hypocalcemia and susceptibility to opportunistic infections. Cardiac malfunctions typically include tetralogy of Fallot, truncus arteriosus, and interrupted aortic arch. Facial signs consist of retromicrognathia, small teeth, short filtrum, hypertelorism, and low-set and malformed ears. Pulmonary, renal, skeletal, ophthalmological, and GI defects can also occur.

Molecular diagnosis is made by using chromosomal microarray or array comparative genomic hybridization or by sequencing the *TBX1* gene. Because of the poor development of the thymic gland, patients with DGS usually have T-cell lymphopenia, which frequently improves with age but may never reach normal levels. A small group of patients are born with little to no detectable circulating T cells and are therefore designated as suffering from "complete DGS." Management is dictated by the presenting features of this heterogeneous syndrome. Calcium supplements and 1,25-cholecalciferol may be needed to treat hypocalcemia. Blood products, if needed (normally during heart surgery), should be CMV-free and irradiated to eliminate allogeneic T-cell transfer and to prevent GvHD. Thymic tissue transplantation has been attempted in cases with complete DGS, although the effects are difficult to evaluate, since children with DGS tend to improve spontaneously with age.

Wiskott-Aldrich Syndrome

Wiskott-Aldrich syndrome (WAS; OMIM #301000) is a rare X-linked recessive condition caused by mutations in the *WAS* gene. The WAS encoded protein is predominately expressed in hematopoietic cells, and its main function is to activate actin assembly by binding to the Arp2/3 complex. The WAS protein (WASP) is required for TCR-mediated formation of the immunological synapse, which is a process dependent on actin rearrangement. Patients are typically diagnosed in infancy, and their condition is characterized by thrombocytopenia, eczema, and recurrent infections.[47] Platelet volume is reduced and appears to be rapidly cleared from the circulation. The abnormal coagulation in these patients is associated with bloody stools and life-threatening intracranial bleeding. Patients with this syndrome occasionally have increased susceptibility to bacterial, viral, and opportunistic organisms, including *P. jiroveci* pneumonia. Autoimmunity and malignancy, particularly lymphoma, have been frequently reported in these patients. T-cell numbers tend to decrease over time, resulting in mild-to-moderate lymphopenia, and *in vitro* responses to mitogens are frequently normal. Typically, IgM is low, IgG is normal, whereas IgA and IgE are elevated. Splenectomy should be avoided. HSCT successfully cures these patients. Gene therapy for this condition is currently being studied.[48] Recently, a patient with a similar phenotype to WAS was shown to have a mutation in the WASP-interacting protein (WIP). WIP stabilizes WASP, preventing its degradation.

Ataxia Telangiectasia (Louis-Bar Syndrome)

Ataxia telangiectasia (AT; OMIM #208900) is an autosomal recessive multisystem disorder characterized by cerebellar ataxia, telangiectasias, immunodeficiency, and highly increased predisposition to malignancy. AT is a result of deleterious mutations in the *ATM* gene (OMIM *607585), which encodes a key protein involved in protecting DNA repair. ATM is a serine/threonine protein kinase that activates signaling pathways upon double-strand breaks, which occur naturally during Ig and TCR rearrangement or upon stress posed by ionizing radiation. It is also involved in cell cycle control and may act as a tumor suppressor gene.

Affected individuals present in early childhood with progressive truncal ataxia, which is frequently misdiagnosed in infancy as cerebral palsy. Choreoathetosis and dystonia, ocular motor apraxia, and dysarthria are common. At 3–5 years of age telangiectasias become increasingly prominent in the eyes and ear lobes. Typically, patients become wheelchair dependent during the second decade of life. Most patients die by the age of 30 years, with rare survivors who live to the end of the fourth decade. Patients die of progressive restrictive lung disease, infections, or cancer. Lymphoma, leukemia, and ovarian and stomach cancers are the most common malignancies associated with AT, and a high risk of developing breast cancer is a prominent feature of heterozygotes.

Diagnosis of this condition is supported by demonstrating increased frequency of chromosomal breakage and elevated levels of alpha-fetoprotein, which reflect the defect in DNA repair and liver tissue immaturity, respectively. Immune investigations show decreased circulating T cells and abnormal *in vitro* response to mitogens. The thymus is dysplastic, and TREC levels are markedly reduced. IgA is low in about 50% of patients, and IgG levels vary from extremely low to normal levels. IgM may be increased, a phenotype mimicking hyper-IgM syndrome (HIGM). The diagnosis is confirmed by identifying mutations in the *ATM* gene. Treatment is mostly supportive and limited to intravenous immunoglobulin (IVIG) and antibiotics, when indicated, as well as physiotherapy. Nijmegen breakage syndrome (OMIM #251260), an AT-like syndrome, is caused by biallelic hypomorphic mutations in *MRE11,* which encodes a protein involved in cell cycle control and double-strand DNA repair. In addition to the typical AT feature, Nijmegen breakage syndrome is characterized by microcephaly, bird-like facial features, and growth retardation.

COMBINED IMMUNODEFICIENCY WITH IMMUNOOSSEOUS DYSPLASIA

This group of combined immunodeficiencies characterized by walking and growth disturbances is summarized in Table 35.6.

Cartilage Hair Hypoplasia

McKusick-type metaphyseal chondrodysplasia, also known as cartilage hair hypoplasia (OMIM #250250), is an autosomal recessive syndrome that was first recognized in the Amish and later in the Finnish population. The condition is characterized by short-limb dwarfism, various degrees of T-cell immunodeficiency, fine and sparse hair, Hirschsprung disease, and increased risk of malignancy. This syndrome is caused by mutations in the RNase MRP (*RMRP*) gene (OMIM *157660), a ribonuclease that is present in both the nucleus and mitochondria. Uniquely, this gene product does not undergo translation but functions as a protein in the cleavage of RNA during mitochondrial DNA synthesis, as well as clearing of nuclear pre-rRNA. Immune function is variable, and patients may present with profound T-cell lymphopenia, depressed mitogenic responses, and a dysplastic thymus. Some cases present with Omenn syndrome (T^+B^+ SCID). Other patients have various degrees of T-cell lymphopenia. Nonimmune features consist of spondylometaphyseal dysplasia, small caliber and hypoplastic hair

TABLE 35.6 Combined Immunodeficiency With Immunoosseous Dysplasia

Disease	Inheritance	Molecular Defect/Presumed Pathogenesis	Features	Treatment
Cartilage hair hypoplasia	AR	Defect in *RMRP* gene resulting in impaired ribosomal assembly and cell cycle regulation	Metaphyseal dysplasia; fine and sparse hair	Hematopoietic stem cell transplantation (HSCT)
Schimke immunoosseous dysplasia	AR	Impaired DNA stress response enzyme	Epiphyseal dysplasia; renal dysfunction; autoimmunity; non-Hodgkin lymphoma	Supportive
Roifman immunoskeletal syndrome (SPENCD)	AR	Impaired tartrate-resistant phosphatase (TRAP) enzyme function, accumulation of phosphorylated osteopontin	Spondyloenchondrodysplasia; autoimmunity; neurological abnormalities	Supportive

with lack of central pigment core, and skin hypopigmentation. There is an increased risk of non-Hodgkin lymphoma and basal cell carcinoma with this syndrome. HSCT has proven curative of the immune abnormalities in these patients.

Schimke Immunoosseous Dysplasia

The major features of Schimke immunoosseous dysplasia (SIOD; OMIM #242900), an autosomal recessive syndrome, are spondyloepiphyseal dysplasia, progressive renal failure, and moderate cellular immunodeficiency. The disease is caused by mutations in the SWI/SNF matrix actin-dependent regulator of chromatin subfamily A-like gene (*SMARCAL1*) encoding a DNA stress response enzyme. Patients with SIOD present with growth retardation before and after birth. In addition to progressive renal failure, patients may have cerebral vascular accidents, dental and skin abnormalities, and dysmorphic features. Immune function is variable, with mild to moderate lymphopenia and somewhat reduced *in vitro* responses to mitogens. Consequently, they develop recurrent viral and fungal infections. Treatment is supportive, and some patients may benefit from renal transplantation.

Roifman Syndrome

Roifman Syndrome (OMIM #616651) was first described as a novel association of immunodeficiency, spondyloepiphyseal chondro-osseous dysplasia, retinal dystrophy, growth and developmental delay, and distinctive facial dysmorphism.[49]

This syndrome is caused by distinct mutations in the small nuclear RNA (snRNA) gene RNU4ATAC (OMIM*601428), which is essential for minor intron splicing. About 800 genes have one or more minor introns, and these are dependent on the minor spliceosome for correct splicing. Since many of these genes are involved in basic cellular functions, such as DNA replication and repair or RNA processing, incorrect splicing can alter cell function and survival. Mutations in the Stem II domain of the gene appear obligatory for this syndrome. Patients with Roifman Syndrome frequently suffer repeated microbial infections such as otitis media, cellulitis and pneumonia as well as viral and fungal infections (HSV, PJP).

Atopy and autoimmune manifestations are also common, including eczema, asthma, arthritis, hemolytic anemia, colitis, and autoimmune hepatitis. Antibody deficiency and hypogammaglobulinemia are present in all cases, and circulating B cells are usually reduced, especially memory B cells. T cell lymphopenia, low CD8+ T cells, abnormal T cell repertoire, as well as low in vitro responses to antigens are also recorded.

Infections are controlled with immunoglobulin replacement in these patients.

SPENCDI–Roifman Immunoskeletal Syndrome

This syndrome was first described in 2000 as a novel combination of features encompassing combined immunodeficiency, autoimmunity, and spondylometaphyseal dysplasia (OMIM # 607944).[50] One patient died of noninfectious encephalopathy, and some others had arthritis, SLE, and thrombocytopenia, in addition to lung disease. Renella et al.[45] highlighted the type of spondylometaphyseal dysplasia as spondyloenchondrodysplasia (SPENCD), confirming the initial observation of autoimmunity in this syndrome. The spectrum of clinical features was further expanded to include cerebral calcifications and other neurological abnormalities. SPENCD is a rare skeletal dysplasia characterized by metaphyseal and vertebral lesions consisting of chondroid tissue. Over the years, evidence for both autosomal dominant and recessive inheritance was proposed. Mice lacking tartrate-resistant phosphatase (TRAP) display skeletal abnormalities identical to the patients. Consequently, sequencing of the *ACP5* gene (OMIM *171640), which encodes TRAP, identified deleterious biallelic mutations in humans.[52,53] Immune abnormalities include T-cell lymphopenia with reduced responses to mitogens and antigens, and an inability to produce specific antibodies. Patients frequently have autoantibodies, such as antinuclear factor (ANF) and anti-DNA. Treatment so far has been limited to replacement of Igs, antibiotics, and immunomodulation of the various immune manifestations.

COMBINED IMMUNODEFICIENCY WITH BONE MARROW FAILURE

Immune deficiencies associated with bone marrow failure are presented in Table 35.7.

IKAROS Deficiency

IKAROS deficiency is extremely rare combined immunodeficiency associated with bone marrow failure (OMIM #616873). IKAROS is a hematopoietic-specific transcription factor (OMIM *603023) affecting pluripotent stem cells that control T-cell differentiation, B-cell V(D)J recombination, and NK-cell development.[54] Patients may present with recurrent pulmonary infections or disseminated viral infections in teenage years, or during infancy with bone marrow aplasia and near absent B and NK cells.[55] T cells can be normal in number, but the response to mitogens is absent

TABLE 35.7 Combined Immunodeficiency With Bone Marrow Failure

Disease	Inheritance	Molecular Defect/Presumed Pathogenesis	Features	Treatment
Dyskeratosis congenita	X-linked, AR, AD	Defective telomere processing proteins, genomic instability	Nail and skin defects; noninfectious enteropathy; developmental delay; microcephaly; cerebellar hypoplasia	Hematopoietic stem cell transplantation (HSCT)
IKAROS deficiency	AD	Impaired lymphocyte development and proliferation, V(D)J rearrangement	Recurrent infections; severe aplastic anemia	HSCT
AK2 deficiency (reticular dysgenesis)	AD	Impaired mitochondrial energy metabolism, severe lymphopenia	Severe marrow failure; bilateral sensorineural deafness	HSCT

TABLE 35.8 Progressive T-Cell Combined Immunodeficiency

Disease	Inheritance	Molecular Defect/Presumed Pathogenesis	Features	Treatment
STAT1 dysfunction	AR, AD	Impaired cytokine signaling	Autoimmunity	Hematopoietic stem cell transplantation (HSCT)
RelB deficiency	AR	Disruption of NF-κB noncanonical pathway	Failure to thrive; autoimmunity	HSCT
STK4 deficiency	AR	Abnormal apoptosis	Epstein-Barr virus (EBV) lymphoproliferation	HSCT

($T^+B^-NK^-$), and Igs are low. The thymus appears large and hyperplastic. HSCT is the only effective treatment proposed.[55]

Dyskeratosis Congenita

Dyskeratosis congenita (DKC; OMIM #305000) is a complex and fatal disorder caused by mutations in genes that encode telomere processing proteins. Inheritance can be X-linked in the case of mutations in dyskerin, the most common cause of DKC, autosomal recessive when mutations in telomerase reverse transcriptase (*TERT*), *NOP10, NHP2,* and *C160ORF57* are found, or autosomal dominant in cases with mutations in telomerase RNA component (*TERC*), *TERT,* and *TNF2.*[56]

Common hallmarks of this group of disorders are bone marrow failure, repeated infections, nail dystrophy, and leukoplakia. Pulmonary fibrosis and colitis are frequently observed. Some patients have additional syndromic features and present early in life with significant intrauterine growth retardation, short stature, microcephaly, and cerebellar hypoplasia, a constellation of features also known as *Hoyeraal-Hreidarsson syndrome.*[57] Other patients present in adolescence or later in life with progressive bone marrow failure. Immune abnormalities are highly variable, with a wide range of presentations from extreme T-cell lymphopenia and occasional profound B-cell lymphopenia (T^-B^- SCID) to mild lymphopenia. Similarly, T-cell function, serum Ig levels, and specific antibody formation are variable. Allogeneic HSCT has been attempted in patients with DKC, primarily for bone marrow failure or malignancy, with disappointing results because of drug toxicity and frequent failure of engraftment.

Moesin Deficiency (MSN Deficiency)

This is a newly described combined immunodeficiency which is inherited in an X-linked manner and caused by mutations in the cytoskeletal protein moesin (OMIM *309845). Moesin is a member of the ezrin-radixin-moesin family of proteins that link the cortical actin filaments to the plasma membrane. The active form of moesin is predominantly expressed in lymphocytes where it is believed to sustain cell shape. Moesin is dephosphorylated upon TCR or BCR binding, suggesting that it plays a role in TCR mediated cell polarization.

Immune evaluation in these patients revealed T cell lymphopenia, hypogammaglobulinemia, antibody deficiency and neutropenia.

Patients are typically susceptible to severe varicella zoster virus and recurrent molluscum contagiosum. Infections were well controlled with replacement immunoglobulin therapy.

PROGRESSIVE T-CELL OR COMBINED IMMUNODEFICIENCY

Immune deficiencies characterized by a progressive decline in T- and/or NK-cell numbers and functions are summarized in Table 35.8.

STAT1 Dysfunction

Mutations in the gene for the DNA-binding transcription factor—*STAT1* (OMIM *600555)—have been associated with an array of different clinical phenotypes ranging from complete deficiencies (autosomal recessive; OMIM #613796), which are fatal in early infancy, to chronic mucocutaneous candidiasis[58,59] or mild persistent oral thrush (autosomal dominant; OMIM #614892). One subgroup of patients with monoallelic *STAT1* mutations appear to have a distinct course. They suffer from repeated and severe viral and fungal infections that are ultimately fatal, and most of them die before the age of 20 years. Most have severe colitis as well as multiple autoimmune features. Evaluation of immunity is normal in these patients, featuring a progressive decline and loss of T cells and NK cells, decreasing T-cell functions, and a structurally abnormal thymus gland. Usually, by the end of the first decade of life, these patients have all of the typical clinical and immunological features of combined immunodeficiency. In this chapter, we will only describe the phenotype of STAT1 dysfunction.

The *STAT1* gene encodes two isoforms, α and β. STAT1β acts as a dominant negative inhibitor, whereas STAT1α plays a critical role in signaling responses to a variety of cytokines, such as interferon-α (IFN-α), IFN-β, IFN; IL-2, -3, -6, -9, -10, -11, -12, and -15; growth hormone fibroblast growth factor; epidermal growth factor; and others. Cytoplasmic STAT1 is activated through tyrosine phosphorylation by members of the JAK kinase family, which results in its translocation to the nucleus and subsequent binding to target DNA segments. Typically, these patients harbor *de novo* mutations in the DNA-binding domain of STAT1. Although increased tyrosine phosphorylation of STAT1 or even enhanced DNA binding may be observed, STAT1 function is altered and patients' cells produce reduced amounts of IL–2, IFN-γ, and other cytokines, hence the designation of STAT1 dysfunction.[60] HSCT has been attempted with variable degrees of success.[61,62]

RelB Deficiency

This is a newly described CID ($T^+B^+NK^+$) that is inherited in an autosomal recessive mode.[63] The immunodeficiency is caused by mutations in *RELB* (OMIM *604758), a key component of the NF-κB pathway. Lymphocyte antigen receptors, multiple cytokines, and infective agents all use the NF-κB signaling pathway.[64] The pathway consists of five members, including RelA, RelB, c-Rel, and the precursor proteins NF-κB1 (p105) and NF-κB2 (p100), which are processed to the active forms p50 and p52, respectively. Two NF-κB pathways are recognized, the classical pathway, mediated by RelA, and the alternative (non-canonical) pathway, which uses RelB. Activation of RelB requires inducible processing of p100 and p52. Unlike the classical pathway, which is engaged by many receptors, the alternative pathway is used by TNFRSF12A, LTβR, CD40, and BAFF-R.[37] Patients with RelB deficiency present in the first year of life with failure to thrive, recurrent infections, and autoimmune disorders. *In vitro* responses to mitogens are depressed, the TCR repertoire is restricted, and TRECs are abnormal. Production of specific antibodies in response to vaccination is impaired. The thymus appears moderately dysplastic. Both memory T and B cells are reduced or absent.[63,65,66] HSCT has been successful in two patients who received the procedure.

STK4 (Mst1) Deficiency

This is an autosomal recessive combined immunodeficiency characterized by a progressive loss of T cells and declining function (OMIM #614868). The deficiency is caused by biallelic mutations in serine threonine kinase 4 (*STK4*). STK4 functions as a pro-apoptotic factor by promoting Fas-mediated apoptosis. STK4-null mice demonstrate increased apoptosis leading to T- and B-cell lymphopenia, as well as depletion of the thymus gland. Patients present with oral thrush and mucocutaneous candidiasis, recurrent bacterial and viral lung infections, and EBV-induced B-cell lymphoproliferation. Skin manifestations include disseminated warts and molluscum contagiosum. Evaluation of the immune system reveals progressive decrease in T and B cells and an altered TCR Vβ repertoire. Serum Igs, including IgE, are elevated, and autoantibodies have been observed. Autoimmune cytopenias have also been reported. HSCT is the treatment of choice.

DIAGNOSIS, MANAGEMENT, AND TREATMENT OF T-CELL AND COMBINED IMMUNODEFICIENCY

The current approach to management and treatment of primary immunodeficiencies involves prevention and treatment of infections, and when attainable, restoration of a functional immune system. Early diagnosis is critical to minimizing morbidity and improving quality of life, and with the increasing implementation of NBSs, patients now have a greater chance of being diagnosed shortly after birth. Importantly, measures that minimize exposure of patients to infections, including use of irradiated and filtered blood products, avoidance of live vaccines, and nutritional support, should also be considered as part of therapy.

THERAPEUTIC PRINCIPLES

Management of Severe Combined Immunodeficiency

- Patients should be kept in a protective isolation environment, receive prophylactic antibiotics, immunoglobulin replacement, and enhanced nutrition.
- Patients should only receive cytomegalovirus (CMV)–free, irradiated blood products and irradiated breast milk. Breast feeding should be discontinued if the mother is CMV positive.
- Live attenuated vaccines should be avoided.
- The immune defect in severe combined immunodeficiency (SCID), and in many cases of combined immunodeficiency (CID), can be corrected by administration of allogeneic hematopoietic stem cell transplantation (HSCT).
- Best results are achieved using an human leukocyte antigen (HLA)–identical family donor.
- Patients with autologous T cell should receive myeloablative conditioning to improve engraftment and sustained long-term immune reconstitution.
- Gene therapy should be offered in selected types of SCID, such as adenosine deaminase (ADA) deficiency, whereas this procedure remains experimental in other conditions.

Newborn Screening

Patients with SCID usually die of overwhelming infections or suffer associated catastrophic complications once maternally transferred antibodies have been metabolized, usually within 3–6 months after birth. However, if diagnosed early and before the onset of complications, most of these patients can be treated successfully with HSCT.

TRECs, which are produced during programmed gene rearrangement of progenitor T cells in the thymus, were identified as a useful biomarker of both thymic function and the production of newly formed T cells. Since the thymus is invariably dysfunctional in SCID, the use of TREC detection in blood from Guthrie spots serves as an ideal NBS tool.[67]

NBS utilizing TRECs detects most cases of phenotypic SCID, especially those who have lymphocytopenia of less than 300–500 $CD3^+$ cells/μL. It may also detect other conditions where the patient presents at birth with profound lymphopenia—such as ataxia telangiectasia, Nijmegen breakage syndrome, Di George syndrome, CHARGE, Rac2 and DOCK8 deficiencies, as well as trisomy.[21]

However, cases that are phenotypically similar to SCID, such as ZAP-70 deficiency or other CIDs with a severe phenotype ($CD3^+$ >300–500 cells/μL) may be missed. This highlights the need consider other methodologies, such as next generation sequencing, which have the capacity to detect these cases at birth.

Isolation

Patients with primary immunodeficiency are susceptible to recurrent and opportunistic infections, posing an immediate threat to life. As a preventative measure, isolation and the provision of an aseptic environment are recommended and have been shown to protect against infections for extended periods. The prevention and successful treatment of infections are strong determinants of HSCT outcome[2] and is associated with decreased frequency of GvHD. In particular, infection prevention is critical in patients with SCID receiving matched unrelated HSCT, where the risk of GvHD has been reported to be >70% (the main cause of morbidity and mortality).[68]

Hematopoietic Stem Cell Transplantation

HSCT is the only potentially curative therapeutic approach for patients SCID and various forms of CID.[69] The replacement of defective HSCs with cells from a healthy donor, typically bone marrow, allows T-cell precursors to repopulate the native thymus and permits reconstitution of a functional immune system. As a result of advancements made in preparing the host, donor cells, conditioning regimens, and supportive therapy, HSCT survival rates have markedly improved since the early 1980s (Chapter 82).

Donor Source

Transplantation involving related HLA-identical donors (RID), usually a sibling, carry the most favorable prognosis, with survival rates of 90 to 100%. Complete immune reconstitution occurs rapidly and carries a low risk of GvHD. However, since such donors are available in less than 20% of cases, donor sources including HLA-matched unrelated donors (MUD) or HLA-mismatched related donors (MMRD) can be considered.

The survival rates for MUD HSCT are greater than 70%,[70] with some centers reporting rates of up to 83%[68,71] and low incidences of GvHD.[72] This modality has proven especially effective in cases with CID. Experience with MMRD HSCT in the past has been disappointing,[73,74] but recent reports suggest improved survival rates for these transplants, although follow-up in many of the cases is still too short.[2] Such transplants involving haploidentical donors require the marrow to be depleted of T cells, and immune reconstitution may be prolonged. Rates of graft failure necessitating a second transplant have been high, along with incomplete immune reconstituation.[72] Complications include opportunistic infections, chronic GVHD, autoimmunity and late deaths.

Nevertheless, regardless of donor source, HSCT prior to 3.5 months of age or before the onset of infection is associated with high rates of survival (95% and 90% respectively) when compared to older children (76%).[2]

Conditioning

Pre-transplant conditioning helps to prepare the recipient marrow for optimal engraftment of donor stem cells and T cell reconstitution, and plays an important role in the long-term outcome of HSCT.[75] Whether conditioning is necessary depends in part on the type of immunodeficiency. For example, whereas myeloablation is necessary for HSCT in patients with sufficient immune cells to reject a graft (as in CID), it may not be indicated for patients with SCID receiving HLA-matched stem cells from a sibling donor. However, it is worth noting that donor B cells rarely engraft in the absence of conditioning regimens, and many patients remain on lifelong immunoglobulin replacement with increased risk of infective lung damage and T lymphocyte senescence.

Myeloablative conditioning with busulfan and cyclophosphamide was once commonly used for HSCT in patients with SCID and CID, although a protocol including busulfan and fludarabine is currently proposed due to risk of veno-occlusive disease (VOD).[76] Alternative conditioning agents include treosulfan (1-treitol-1,4-bis-methanesulfonate), which has both myeloablative and immunosuppressive properties, as well as an improved patient safety profile.

Reduced intensity conditioning (RIC) involving incomplete ablation of the bone marrow may also be beneficial in permitting engraftment and immune reconstitution. However, where such regimens may offer improved survival and reduced toxicity, there have also been reports of increased incidences of mixed donor chimerism and graft failure. In these instances, repeat HSCT or donor lymphocyte infusions may be necessary, which may pose further risk to patients.[77]

HSCT without conditioning has been attempted in patients who are too sick to tolerate pre-transplant chemoablation, however, this is associated with a high frequency of complications and mortality.[78] In such circumstances, it is recommended that the patient be stabilized until a full protocol can be implemented.

Prophylaxis and Treatment of Graft versus Host Disease

GvHD is caused by T cell mediated attack of the host tissue by the graft, and is a significant cause of morbidity and mortality to allogeneic HSCT recipients. The principal affected organs are skin, gastrointestinal tract and liver, with the current grading system (grades I-IV) based upon the extent of organ involvement.[79] Risk factors for GvHD include donor-host incompatibility as well as the source of stem cells, and can be significantly reduced by introducing prophylactic immunosuppression and depletion of donor T cells before infusion. The primary response to such first-line treatment is the most important predictor of long term survival in patients with acute GvHD.

Options for pharmacologic prophylaxis include monotherapy with a calcineurin inhibitor (such as cyclosporine or tacrolimus), or in combination with steroids, methotrexate or mycopholate mofetil. The efficacy of steroids in improving the outcome and probability of survival is well documented.[80,81]

T cell depletion is recommended for HSCT involving HLA-mismatched donors. However, while depletion of donor T cells using physical separation techniques, monoclonal antibodies or anti-thymocyte globulin can reduce GvHD, it is also associated with delayed immune reconstitution and an increased incidence of post-transplant lymphoproliferative disorders and life-threatening infections.[79]

Gene Therapy

Gene therapy represents a therapeutic option for patients with primary immunodeficiency who lack a HLA-identical donor[62] (Chapter 85). By using retroviruses to introduce a functional copy of the defective gene into the patient's own HSCs, this technique negates the need for a donor and is not associated with complications normally arising from HLA-incompatibility.

To date, gene therapy has been demonstrated to be extremely effective in treating patients with ADA deficiency, resulting in a variable increase in T and B cell numbers as well as significant improvement of immune function. Importantly, there have been no reports of serious adverse events or malignancy to this indication.[23]

However, early attempts to utilize gene therapy in other forms of primary immunodeficiency were met with mixed results, and highlighted various pitfalls related to the first-generation vectors.[83] A number of serious adverse events, including leukemia, were caused by preferential integration of retroviral vectors in the proximity of transcription initiation sites, leading to increased and deregulated expression of oncogenes. Use of a γ-retrovirus vector in patients with Wiskott-Aldrich syndrome resulted in partial or complete resolution of immunodeficiency, however 7 of the 10 patients receiving gene therapy developed malignancy.[84] Furthermore, in patients with chronic granulomatous disease, long term immune reconstitution was variable and myelodysplastic syndrome was reported in 3 of 10 patients. Between 1999 and 2006, trials for IL2RG deficiency initially reported successful immune reconstitution in 18 of 20 recipients; however clonal proliferation caused by insertional mutagenesis occurred in 5 recipients after 2 to 5 years.[85] Taken together, these results prompted a discontinuation of these trials, and a call to develop novel and much safer vector constructs, including self-inactivating γ-retrovirus and lentiviral vectors. To date, follow-up studies in patients with IL2RG deficiency utilizing a self-inactivating γ-retrovirus vector have so far been encouraging, with reports of excellent immune reconstitution and no evidence of insertional mutagenesis.[83] In an ongoing study,[48] the application of lentiviral vectors in Wiskott-Aldrich syndrome have demonstrated multilineage engraftment of corrected cells, both in the bone marrow and peripheral blood, with no reports of clonal expansion or leukemia.

With the advancement in technology and progress made in vector design, gene therapy is a viable option for challenging forms of primary immunodeficiency, in which current available treatments are insufficient.

Gene Editing

Gene editing technologies allow precise correction of the defective genomic DNA site and are thus a promising alternative to HSCT (Chapter 85). Using engineered endonucleases, such CRISPR/Cas9, zinc finger nucleases, and transcription activator-like effector nucleases, double-stranded breaks are introduced into specific sequences of the genomic DNA and repaired through homology-directed repair. In the presence of a DNA repair template containing a functional version of the defective gene, the double-stranded break is accurately repaired with the corrected sequence incorporated. While gene editing provides greater control over site integration than retrovirus-based gene therapy, the technique is still in the pre-clinical phase, with developments being made to limit errors such as off-target mutagenesis. To date, zinc finger nucleases have been utilized to correct IL2RG mutational hotspots in hematopoietic and embryonic stem cells.[86,87] Transplantation of these cells into immunodeficient mice resulted in multilineage hematopoietic differentiation.[86] Successful attempts to correct SCID patient-specific induced pluripotent stem cells in-vitro have also been reported, although further studies are needed to address the tumorigenic potential of such cells.

CONCLUSIONS

The traditional clinical and laboratory definitions of profound T-cell deficiencies, although still helpful in many cases, are no longer sufficient. This is highlighted by gene defects, such as FOXP3 deficiency, a fatal T-cell deficiency with normal *in vitro* responses to mitogens as well as TREC levels. It is, therefore, important to broaden our definitions to include severe autoimmune/inflammatory conditions as main or prominent clinical features of profound T-cell deficiency, in addition to recurrent opportunistic infections and susceptibility to specific infectious agents. Other clinical features, such as granulomata and lymphoma, have also been reported recently as sole manifestations of T-cell immunodeficiencies. With the increased recognition of genetic aberrations linked to these diseases, we are likely to see a great expansion of novel phenotypes associated with known genotypes, although not necessarily with identical mutations.

ON THE HORIZON

- Whole exome sequencing can be technically performed using DNA derived from a dried blood spot. Implementing this technology to newborn screening will immensely improve the outcome of patients.
- In the future, closer attention will be paid to family members of patients with overt immunodeficiency to better understand the clinical impact of monoallelic/carrier genetic aberrations.
- Whole exome sequencing is widely reported to be successful in only 40% of cases. Whole-genome sequencing and development of new bioinformatics algorithms would likely yield better results.
- Although hematopoietic stem cell transplantation can cure patients with T-cell deficiency, in many cases, it remains a high-risk procedure and may not be optimal therapy for a growing number of newly defined combined immunodeficiencies. New developments in gene therapy and gene editing are likely to expand as alternative treatments.

This expansion in diagnosis of profound T-cell deficiencies raises new opportunities to study mechanisms underlying autoimmunity as well as lymphoid malignancies. However, these cases may pose new challenges, such as choice of HSC therapy. Further prospective trials should help to determine the validity of transplantation compared with conservative immunosuppressive therapy or innovative new biological treatments.

With challenges come opportunities, and we are living in an exciting era of improved tools to enhance the understanding of the molecular changes and mechanisms leading to profound T-cell deficiency and associated autoimmunity and malignancy. This wealth of knowledge should help advance novel treatments.

MULTIPLE-CHOICE QUESTIONS

1. Each of these comments about T-cell deficiencies (severe combined immunodeficiency/combined immunodeficiency [SCID/CID]) are TRUE, except:
   A. Patients may present in infancy with failure to thrive.
   B. The thymus always appears dysplastic.
   C. Malignancy could be the sole presenting feature.
   D. Clinical manifestations may first arise during late childhood or adolescence.
   E. Patients may present with severe hypocalcaemia.

2. Which of the following is INCORRECT?
   A. All patients who present with a SCID phenotype can be detected at birth by T-cell receptor excision circle (TREC) analysis
   B. *In vitro* responses to mitogens can be normal in some cases.
   C. Evaluation of natural killer (NK) cell numbers and function can be beneficial for diagnosis.
   D. Serum immunoglobulin levels can be normal.
   E. CH50 does not contribute to the diagnosis.

3. For which of the following conditions is hematopoietic stem cell transplantation not recommended?
   A. FOXP3 deficiency
   B. Ataxia telangiectasia
   C. Major histocompatibility complex (MHC) class II deficiency
   D. Adenosine deaminase (ADA) deficiency
   E. DOCK2 deficiency

Immunodeficiencies at the Interface of Innate and Adaptive Immunity

Jacinta Bustamante, Shen-Ying Zhang, Bertrand Boisson, Michael Ciancanelli,
Emmanuelle Jouanguy, Stéphanie Dupuis-Boisson, Anne Puel, Capucine Picard,
Jean-Laurent Casanova

In the last 20 years, new primary immunodeficiencies (PIDs) affecting the immunity mediated by interferon (IFN)- γ, IFN-α/β-λ, Toll and interleukin-1 receptor (TIR) domain nuclear factor (NF)-κB, Toll-like receptor (TLR)-3 pathway, and interleukin (IL)-17 have been identified. Some of these genetic defects are "conventional" PIDs, associated with a broad range of infections, but others provide a molecular explanation for severe pediatric infectious diseases previously thought to be idiopathic (Table 36.1). These "nonconventional" PIDs may be associated with severe and/or recurrent infections caused by a single family of microorganisms, a situation strongly contrasting with that for "conventional" PIDs. Standard immunological explorations are generally normal in these patients, whether they are susceptible to one or many infectious agents. Despite the lack of a clear immunological abnormality, infections in these patients are typically severe, and often fatal. This chapter is devoted to the description of these PIDs. They include disorders of the IFN-γ circuit associated with the syndrome of mendelian susceptibility to mycobacterial disease (MSMD).[1,2] Combined disorders of IFN-γ- and IFN-α/β-λ-mediated immunity are associated with mycobacterial and viral diseases. We also describe genetic defects affecting primarily the TLR-3 pathway.[3-9] The predominant infectious phenotype of patients with these defects is herpes simplex virus (HSV)-1 encephalitis (HSE) in childhood. We discovered the first genetic defect associated with severe isolated influenza, and mutation of *IRF7.*[10] We describe four PIDs associated with impaired signaling downstream from or via the TIR canonical pathway as a result of mutations of *IRAK4, MYD88, NEMO,* and *NFKBIA.*[11-15] Mutations of *NEMO* and *NFKBIA* also impair the alternative, Toll/IL-1R homologous region (TIR) domain–containing adapter-inducing IFN-β (TRIF)–dependent pathway.[16] The principal infectious phenotype of patients with any of these defects is the occurrence of pyogenic bacterial infections. Finally, we have described a new group of defects affecting IL-17 pathways and conferring predisposition to chronic mucocutaneous candidiasis (CMC).[17-20] All these disorders were initially thought to be rare, but they have since been diagnosed in about 800 patients around the world (see Table 36.1).

KEY CONCEPTS

- New primary immunodeficiencies (PIDs) should be sought in patients with unexplained infectious diseases.
- Children with severe infectious diseases should be repeatedly investigated for known and unknown immunodeficiency conditions.
- The exploration of idiopathic infections leads to the discovery of new PIDs and to a better understanding of immunity to pathogens.

MENDELIAN SUSCEPTIBILITY TO MYCOBACTERIAL DISEASE: GENETIC DISORDERS OF THE IFN-γ CIRCUIT

Genetic disorders of the IFN-γ circuit are associated with a selective susceptibility to weakly pathogenic mycobacteria, such as environmental mycobacteria (EM) and/or Bacille Calmette-Guérin (BCG) vaccines, and *Salmonella* (MSMD, Online mendelian Inheritance in Man [OMIM]: 209950) (Fig. 36.1).[21] These PIDs are caused by mutations in 10 genes involved in IFN-γ–mediated immunity: *IFNGR1* and *IFNGR2,* encoding the two chains of the receptor for IFN-γ, a pleiotropic cytokine secreted by natural killer (NK) and T cells; *STAT1,* encoding a transcription factor essential to the IFN-γR signaling pathway; *IL12B,* encoding the p40 subunit of IL-12 and IL-23, IFN-γ–induced cytokines secreted by macrophages and dendritic cells (DCs); *IL12RB1,* encoding the β_1 chain of the receptor for IL-12 and IL-23, which is expressed on NK and T cells; *NEMO,* encoding NF-κB essential modulator (NEMO), which is involved in the CD40-dependent induction of IL-12; *IRF8,* encoding an IFN regulatory factor inducible by IFN-γ; *TYK2,* which is involved in IL-12–dependent IFN-γ immunity; and *ISG15,* encoding an IFN-γ-inducing molecule that acts in synergy with IL-12.[1,2] The MSMD-causing mutations in *CYBB* affect the respiratory burst selectively in macrophages.[22] Some mutations of *STAT1* and most mutations of *NEMO* are associated with a much broader range of infectious diseases (see below), and complete interferon regulatory factor-8 (IRF8) deficiency is associated with a lack of circulating monocytes and DCs, and severe clinical disease, mimicking combined immunodeficiency (CID).[1,23,24] The molecular and clinical features of MSMD have been reviewed elsewhere.[1]

Complete IFN-γR1 and IFN-γR2 Deficiencies

Autosomal recessive (AR) complete IFN-γ receptor 1 (IFN-γR1) deficiency (OMIM 107470) is caused by recessive null *IFNGR1* mutations precluding the expression of IFN-γR1 on the cell surface or the recognition of its ligand, IFN-γ, by surface-expressed receptors. Affected patients fail to respond to IFN-γ and have high serum concentrations of IFN-γ after infection.[1] Mutations of the *IFNGR2* gene encoding IFN-γR2 lead to a complete loss of cellular responsiveness to IFN-γ because of a lack of receptor

HSE, herpes simplex encephalitis; EDA, ectodermal anhidrotic dysplasia; AR, autosomal recessive; N, normal; AD, autosomal dominant; VZV, varicella-zoster virus; HSV-1, herpes simplex virus type 1; XR, X-recessive.

[a] one patient with AD IFN-γR1 deficiency presented one episode of *Histoplasma capsulatum* infection, and another patient presented coccidioidomycosis.

[b] one patient with IL-12Rβ1 deficiency presented one episode of *Paracoccidioides brasiliensis* infection, and some patients display forms of chronic mucocutaneous candidiasis.

expression or the expression on the cell surface of nonfunctional receptors (OMIM 147569). All known patients have suffered from disseminated infections caused by EM and/or BCG, with impaired granuloma formation, all requiring continuous multidrug therapy (Fig. 36.2A).[1,25] Infections usually began early in life, often before the age of 3 years. The immunological features of patients with IFN-γR2 deficiency are essentially indistinguishable from those of patients with AR complete IFN-γR1 deficiency. A few of these patients have presented with nontyphoidal salmonellosis, and one presented with recurrent invasive infections with *Listeria monocytogenes.*[25] Viral infections caused by cytomegalovirus (CMV), human herpes virus 8 (HHV-8), respiratory syncytial virus (RSV), pseudorabies virus 3 (PRV-3), and varicella-zoster virus (VZV) have been described in some patients. One patient had a fatal HHV-8–driven Kaposi sarcoma, a second had a pineal germinoma, and a third had a cutaneous squamous cell carcinoma.[1] Multiple antibiotics against mycobacteria should be administered without interruption. Vaccination with live BCG is contraindicated. The prognosis is very poor in the absence of hematopoietic stem cell transplantation (HSCT).[25] HSCT is best carried out once mycobacterial disease has been controlled.[26] HSCT is the only curative treatment for these patients but has proven to be associated with an unusually high rate of graft rejection, making transplantation particularly difficult.[1]

Autosomal Recessive Partial IFN-γR1 and IFN-γR2 Deficiencies

Fifteen patients from 12 unrelated kindred with AR partial IFN-γR1 deficiency (OMIM 107470) have been identified.[27] Two mutations affecting the extracellular domain of IFN-γR1 have been identified: V63G and I87T. Founder effects accounted for the recurrence of both mutations. Patients with AR partial IFN-γR1 deficiency have a less severe clinical phenotype than patients with AR complete IFN-γR1 deficiency. Disseminated BCG was observed in five patients. One patient, who had not been vaccinated with BCG, had curable symptomatic primary tuberculosis (TB). *Mycobacterium abscessus* caused a disseminated infection in one patient. Other nonmycobacterial infections caused by bacteria (*Salmonella, Shigella sonnei, Haemophilus influenzae, Legionella* spp., *Mycoplasma pneumoniae,* and *Klebsiella* spp.), viruses (VZV, RSV, *Molluscum contagiosum*), and parasites (*Toxoplasma gondii, Cryptosporidium*) have been reported. The

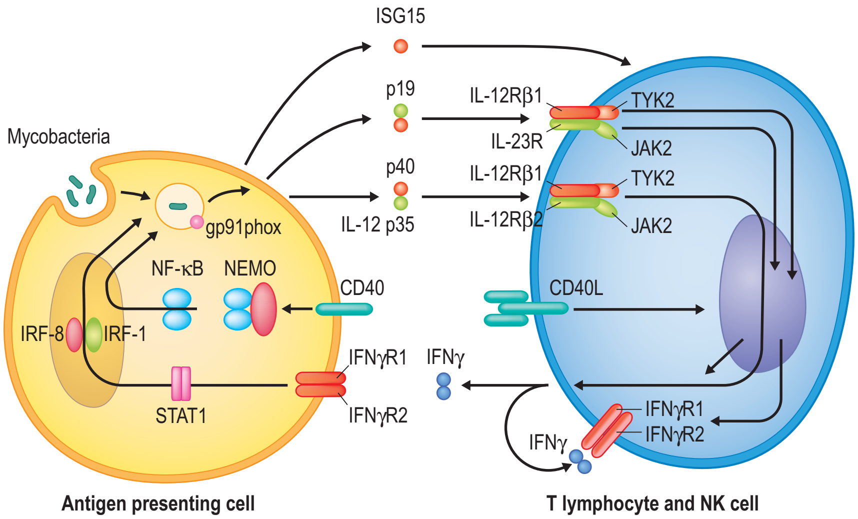

FIG 36.1 Genetic Etiologies of Mendelian Susceptibility to Mycobacterial Disease (MSMD). IL-12 is secreted principally by phagocytes and dendritic cells (DCs) and binds to a receptor consisting of a heterodimer of β_1 and β_2 chains that is expressed specifically on natural killer (NK) and T lymphocytes. IFN-γ is secreted by NK and T lymphocytes and binds to a ubiquitous receptor consisting of two chains, a ligand-binding (IFN-γR1) and a signaling-associated chain (IFN-γR2). Signal transducer and activator of transcription 1 is phosphorylated in response to IFN-γ and is translocated to the nucleus as a homodimer. Nuclear factor (NF)-κB essential modulator (NEMO) is a regulatory protein in the NF-κB pathway. The engagement of CD40 signaling via the NF-κB pathway is important for IL-12 production and for protective immunity against mycobacterial infection. Interferon regulatory factor-8 (IRF8) is an IFN-γ–inducible transcription factor required for the induction of various target genes, including IL-12. TYK2 is necessary for the response to IL-12 in T lymphocytes and NK cells. Gp91^{phox} is a key component of the phagocyte nicotinamide adenine dinucleotide phosphate (NADPH) oxidase.

affected patients had well circumscribed and differentiated tuberculoid granulomas (Fig. 36.2B). The cellular phenotype is characterized by an impaired response to high concentrations of IFN-γ, with receptor expression on the cell surface. Five mutations in six patients with PR IFN-γR2 deficiency (OMIM 147569) have also been reported.[1] Patients have had BCG, *M. abscessus, M. bovis, M. elephantis, M. fortuitum,* and *M. simiae* infections. The patients had high plasma IFN-γ concentrations, and various cell types displayed an impaired response to IFN-γ. All hypomorphic mutations of *IFNGR2* lead to abnormally high levels of N-glycosylation of the corresponding protein and its retention in the endoplasmic reticulum (ER).[28] Thus a diagnosis of PR IFN-γR1 or IFN-γR2 deficiency should be considered in children and adults with mycobacterial infections and a mild clinical and histological phenotype.[1,28] For these patients, antimycobacterial treatment can eventually be stopped, but not within the first year after the infection is brought under control. Recombinant IFN-γ is indicated for the treatment of PR IFN-γR deficiencies. Patients should then be closely monitored. HSCT is not indicated, given the relatively mild infectious phenotype.[1]

Autosomal Dominant Partial IFN-γR1 and IFN-γR2 Deficiencies

More than 70 patients were found to have autosomal dominant (AD) partial IFN-γR1 deficiency (OMIM 107470).[1] These patients have a heterozygous small frameshift deletion in *IFNGR1,* most bearing the same 818del4 heterozygous mutation (or another mutation in the same region), downstream from the segment encoding the transmembrane domain, but upstream from the recycling motif and JAK1 and STAT1 docking sites. This heterozygous mutation defines the first hotspot for small deletions. It is dominant negative and decreases cellular responses to IFN-γ in heterozygous cells and patients. The clinical phenotype is characterized by EM and BCG infections, often affecting the bones.[1,25] A diagnosis of mycobacterial osteomyelitis is highly suggestive of AD IFN-γR1 deficiency.[25] Only 5% of the patients in the largest cohort of patients with heterozygous 818del4 ever published have presented with nontyphoidal salmonellosis, one has presented a single episode of infection with *Histoplasma capsulatum,* eight are asymptomatic, and two died of disseminated mycobacterial infection at the ages of 17 and 27 years, respectively. Antimycobacterial antibiotic treatment could be combined with IFN-γ injection in cases of disseminated infection. Antibiotics can be stopped, but not within the first year after the infection is brought under control. Vaccination with live BCG is contraindicated. The clinical outcome of patients with AD IFN-γR1 deficiency, like that of patients with AR partial IFN-γR1 and IFN-γR2 deficiencies, is much better than that of children with AR complete IFN-γR deficiency because there is some residual IFN-γ signaling. There is, therefore, a strict correlation between *IFNGR1* genotype and cellular and clinical phenotype.[25]

One heterozygous mutation of *IFNGR2* has been reported to contribute to an AD form of partial IFN-γR2 deficiency.[29] This mutation, 186delC, creates a premature codon stop upstream from the segment encoding the transmembrane domain. The affected patient had a mild form of mycobacterial infectious disease, and her father was asymptomatic. Haploinsufficiency of the *IFNGR2* locus was observed in Epstein-Barr virus (EBV) B cells and T lymphocytes.[29]

Complete IL-12Rβ1 and IL-12P40 Deficiencies

More than 200 patients with AR complete IL-12 receptor β1 (IL-12Rβ1) deficiency (OMIN 601604), with no cellular expression or with expression of the mutated form, have been identified.[1,30] The cellular phenotype of patients with IL-12Rβ1 deficiency is a lack of response of natural killer (NK) and T lymphocytes to IL-12 and IL-23, resulting in low levels of IFN-γ production. The clinical phenotype is characterized by EM/BCG infections, with half the patients also presenting nontyphoidal salmonellosis.[30] Most of the children inoculated with live BCG vaccine

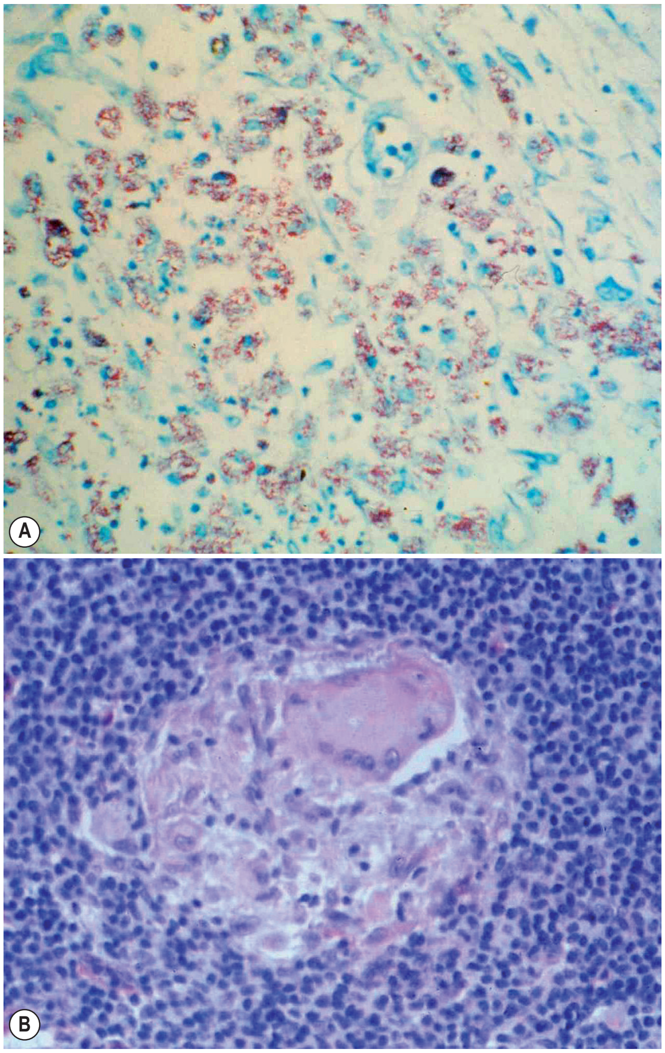

FIG 36.2 **Two Types of Granuloma.** (A) The lepromatous-like type consists of poorly defined, poorly differentiated granulomas, with few, if any giant cells and lymphocytes, but widespread macrophages loaded with acid-fast bacilli. (B) The tuberculoid type consists of well circumscribed and differentiated granulomas, with epithelioid and multinucleated giant cells containing very few acid-fast rods, surrounded by lymphocytes and fibrosis, occasionally with central caseous necrosis.

developed clinical infection, and other mycobacterial infections are caused by EM (alone or associated with other infections) or by *M. tuberculosis.* The low penetrance for the case-definition phenotype of BCG/EM disease led to the discovery of tuberculosis as the sole infectious phenotype in several patients, providing the first cases of mendelian predisposition to tuberculosis. Infections caused by *Paracoccidioides brasiliensis, Coccidioides* spp., *Histoplasma* spp., *Cryptococcus neoformans, Toxoplasma* spp., and *Leishmania* spp. have been reported in a few cases. A substantial fraction of patients with IL-12Rβ1 deficiency present mild forms of CMC,[30-32] an observation probably related to the impairment of the IL-23–IL-17 circuit in these patients. All the survivors were well in 2010, when the oldest of these patients was 51 years old.[1,30]

Fifty patients with AR complete IL-12p40 deficiency (OMIM 161561) have been reported.[1,33] Children with this deficiency produce abnormally low levels of IFN-γ because of a lack of stimulation through the IL-12R. This defect can be partially corrected, in a dose-dependent manner, with exogenous recombinant IFN-γ.[1,33] All children inoculated with live BCG vaccine developed clinical infection, and infections caused by EM or *M. tuberculosis* have also been reported. Other infections, such as salmonellosis, klebsiellosis, and nocardiosis, have been described. Five of the reported patients are asymptomatic. Thirteen of the 50 patients died before the age of 8 years, and one patient died at the age of 34 years.[1,33]

For IL-12p40 and IL-12Rβ1 deficiencies, antibiotic treatment can be combined with IFN-γ injection in cases of disseminated infection.[1] Antibiotics can be stopped, but not within the first year after the infection is brought under control. Infectious *Salmonella* disease should be treated with antibiotics or with IFN-γ and antibiotics in patients with recurrent salmonellosis. Thus a diagnosis of IL-12p40 or IL-12Rβ1 deficiency should be considered in children and adults with mycobacterial and *Salmonella* infections or mycobacterial infections and CMC with a mild clinical and histological phenotype. The vaccination of these patients with live BCG is contraindicated.[1,33] The prognosis is, nevertheless, good, partly because of the incomplete clinical penetrance of primary mycobacterial infection, the favorable response of infections to treatment, and the rarity of recurrent or multiple mycobacterial infections. Indeed, children with primary mycobacterial disease can mount a fully protective immune response against a secondary mycobacterial disease.

THERAPEUTIC PRINCIPLES

Treatment of Mendelian Susceptibility to Mycobacterial Disease (MSMD) Patients

- Vaccination with live Bacille Calmette-Guérin (BCG) is contraindicated.
- Multiple antibiotics against mycobacteria should be administered without interruption in patients with complete interferon (IFN)-γR1 or IFN-γR2 deficiency.
- Antimycobacterial antibiotics may be associated with IFN-γ injections in selected patients with partial IFN-γR1, IFN-γR2, IRF8, CYBB, or signal transducer and activator of transcription 1 (STAT1) deficiency, complete interleukin (IL)-12p40, IL-12Rβ1, or ISG15 deficiency.
- Hematopoietic stem cell transplantation (HSCT) should be considered in selected patients with complete IFN-γR1 or IFN-γR2 deficiency.

Autosomal Dominant Partial STAT1 Deficiency

Nine kindreds with 21 genetically affected cases have been reported to have heterozygous mutations in *STAT1* causing AD partial STAT1 deficiency (OMIM 600555).[1,24] STAT1 is a critical transducer of IFN-mediated signals, either as STAT1 homodimers (γ-activating factor [GAF]) or as STAT1/ STAT2/IRF9 trimers (IFN-stimulated gene factor 3 or ISGF3) (Fig. 36.3). These heterozygous *STAT1* mutations reduce the cellular response to IFN-γ, but not that to IFN-α.[24] Mycobacterial infections caused by BCG, EM, or TB are observed, ranging from local to disseminated disease. Osteomyelitis is frequent in these patients (eight of 15 patients).[1] The other six patients are asymptomatic. All patients were well at their last evaluations and were between four and 38 years old in 2005. Antimycobacterial treatment can be stopped, but not during the first year after the infection is brought under control. Vaccination with live BCG is contraindicated. Observations of affected patients have suggested that STAT1 and GAF are required for human IFN-γ-mediated mycobacterial immunity. In conclusion, patients with AD STAT1 deficiency have clinical and cellular phenotypes (*i.e.,* susceptibility

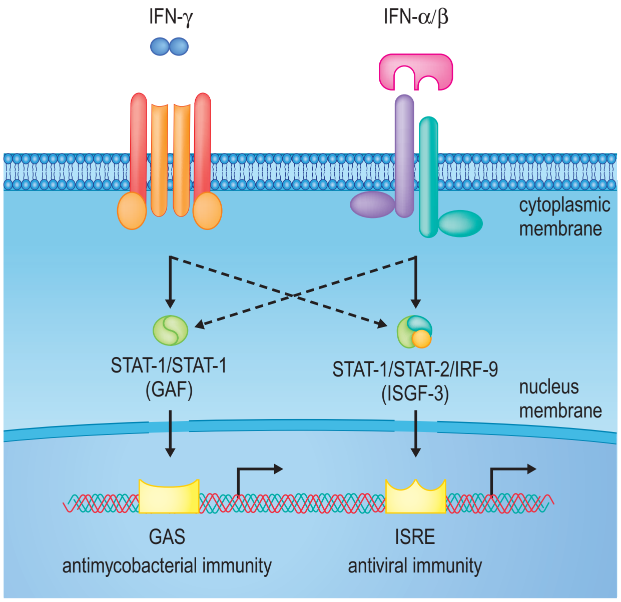

FIG 36.3 STAT-1 Pathway. The binding of homodimeric IFN-γ to its tetrameric receptor leads to activation of the constitutively associated JAK kinases JAK1 and JAK2, which then phosphorylate tyrosine residues in the intracellular part of interferon (IFN)-γR1. Upon IFN-γ stimulation, unphosphorylated signal transducer and activator of transcription 1 (STAT1) molecules are directly recruited to IFN-γR1 docking sites. They are then phosphorylated and released into the cytosol as phosphorylated STAT1 homodimers. These homodimers form γ-activating factor (GAF), which is translocated to the nucleus. GAF binds γ-activating sequences (GAS) present in the promoters of target genes. Following monomeric IFN-α/β stimulation, STAT2 is recruited to the phosphorylated IFN-αR1 chain of the heterodimeric IFN-αR, which is in turn phosphorylated by JAK1 and TYK2. This leads to the phosphorylated STAT2-mediated recruitment of STAT1, which is then phosphorylated. Active phosphorylated STAT1/STAT2 heterodimers are released into the cytosol and translocated to the nucleus with interferon regulatory factor-9 (IRF-9), to form interferon-stimulated gene factor-3 (ISGF-3) heterotrimers. ISGF-3 binds IFN-α/β sequence response elements (ISRE) in the promoters of target genes via the DNA-binding domains of STAT1 and IRF9. In humans, recessive complete STAT1 deficiency results in impaired responses to both IFN-γ and -α/β. It is associated with a specific syndrome, different from mendelian susceptibility to mycobacterial disease (MSMD), of susceptibility to both mycobacteria (impaired IFN-γ-mediated immunity) and viruses (impaired IFN-α/β-mediated immunity).

to mycobacterial disease, osteomyelitis in particular, and impaired GAF activation) similar to those of patients with AD IFN-γR1 deficiency. These patients should be treated in a similar manner.[1]

Complete and Partial IRF8 Deficiency

Two types of IRF8 deficiency have been reported in the last few years (OMIM 601565).[23] Disseminated BCG disease in a child born to consanguineous parents led to the discovery of a lack of circulating monocytes and DCs. The severity of the disease, mimicking CID, rendered HSCT necessary.[1,23] Candidate gene studies showed that the child had AR complete IRF8 deficiency. The IFN-γ circuit was, therefore, profoundly disrupted. Other mechanisms may account for BCG disease and vulnerability to other infectious agents. In two other patients with a history of pure MSMD, the same heterozygous mutation, T80A, was found in *IRF8*, defining an AD IRF8 deficiency.[23] The mutation was severely hypomorphic and dominant negative. Interestingly, the IFN-γ circuit did not appear to be disrupted in tests on whole blood. Nevertheless, the two unrelated patients with AD IRF8 deficiency lacked circulating CD1c CD11c DCs.[23] This population of cells produces large amounts of IL-12 in normal individuals, and its absence therefore probably contributed to the MSMD phenotype.

AR Complete ISG15 Deficiency

Recently, six patients with complete AR ISG15 deficiency have been identified (OMIM 616126).[34,35] Three of the six patients suffered from clinical disease caused by BCG vaccine. The only features common to all patients were calcifications of the basal ganglia in the brain. The cellular phenotype was characterized by an impaired, but not abolished, IFN-γ production upon whole blood activation by BCG plus IL-12, as seen in patients with IL-12p40 or IL-12Rβ1 deficiency.[1,34,35] The addition of recombinant ISG15 rescued the production of IFN-γ by T and NK cells of the patients. A high level of ISG mRNA was detected in all patients with ISG15 deficiency. The absence of intracellular ISG15 in the patients' cells prevents the accumulation of USP18, a potent regulator of IFN-α/β signaling, and amplifies the IFN-α/β induced responses. This novel MSMD-causing gene acts like both an IFN-γ–inducing secreted cytokine and an intracellular negative regulator of IFN-α/β.[34,35] These patients display not only MSMD but also a novel form of type I interferonopathy because intracellular human (but not mouse) ISG15 is paradoxically a negative regulator of IFN immunity.

AR Complete TYK2 Deficiency

AR complete TYK2 deficiency was first described in a Japanese patient as a genetic etiology of hyper-immunoglobulin E (IgE) syndrome in 2006 (OMIM 176941). However, five more families and seven more patients have since been described.[2] The patients harbor homozygous nonsense mutations, deletions, or insertions generating a premature stop codon and resulting in undetectable levels of the TYK2 protein.[2,36] Clinically, all the patients display mycobacterial and/or viral diseases, which appear to be the main clinical features of AR complete TYK2 deficiency. One patient suffered only from BCGosis, two only from tuberculosis, one only from HSV meningitis, three had mycobacterial and viral diseases, and one had meningitis of unknown origin, although all were vaccinated with BCG and had probably encountered the common viruses of childhood.[2] The patients' cells display an impaired, but not abolished response to IL-12/IL-23 and IFN-α/β, almost certainly accounting for their susceptibility to mycobacteria and viruses, respectively. The response to IL-10 is weak, but with no overt clinical manifestations. An impaired response to IL-23 is also observed, preventing the differentiation of abolished CD4 T cell response into Th17 cells *in vitro*, but the patients have normal levels of circulating IL-17$^+$ T cells, probably accounting for their lack of CMC.[2] An intact response to IL-6 has been observed in all patients except for the first patient described, who displayed the symptoms of hyper-IgE syndrome. The impaired response to IL-6 in this patient was found to be independent of WT-TYK2 expression, potentially accounting for some of the unusual clinical features in this patient. Overall, AR complete TYK2 deficiency leads to isolated or combined mycobacterial and viral diseases.[2]

NEMO and *CYBB* Deficiencies

An X-linked recessive (XR) form of MSMD (XR-MSMD) (OMIM 300248) was discovered in three unrelated kindreds. This condition was caused by two neighboring mutations (E315A and R319Q) in *NEMO*.[1,37] These two missense mutations, which affect two neighboring residues in the leucine zipper domain that normally form a salt bridge, were entirely responsible for impairment of the CD40-triggered induction of IL-12 production by monocyte-derived cells following stimulation with CD40L-expressing T cells. Four maternally related male patients from two successive generations presented *M. avium* infection only, and the other two, unrelated patients presented only mycobacterial disease. These patients had a purely mycobacterial infectious phenotype, with no sign of anhidrotic ectodermal dysplasia (EDA).[1,37]

A second form of XR MSMD has been reported (OMIM 300645)[22] in seven patients from two unrelated French families. The *CYBB* or gp91^{phox} mutations identified in these patients were previously unknown and affect the transmembrane domain and an extracellular loop. *CYBB* encodes the major component of the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase complex.[22] Mutations in any of the genes encoding molecules from this complex generally result in chronic granulomatous disease (CGD). However, unlike the cells of patients with CGD, neutrophils, monocytes, and monocyte-derived dendritic cells (MDDCs) from these seven patients with XR MSMD displayed perfectly normal levels of NADPH oxidase activity.[22] These patients produce only small amounts of neutrophil and monocyte gp91^{phox} protein, but normal amounts of cytochrome b_{558}. However, monocyte-derived macrophages and EBV-B cells display much more profound defects of gp91 ^{phox} expression, resulting in impaired cytochrome b_{558} assembly and low levels of NADPH oxidase activity.[22] Thus NADPH oxidase activity in human macrophages is a crucial effector mechanism for protective immunity to tuberculous mycobacteria. None of the seven patients suffered from any other infectious diseases. These patients are all adults and are currently well. Vaccination with live BCG is contraindicated in patients with these deficiencies. None of the patients described, to date, has had prophylactic treatment. Infections can be treated with multiple antibiotics.[1]

INHERITED DISORDERS OF IFN-γ– AND IFN-α/β–MEDIATED IMMUNITY

AR Complete and Partial STAT1 Deficiency

Nine children from six unrelated kindreds with AR complete STAT1 deficiency (OMIM 600555) have also been identified[24] (unpublished data). These patients carried homozygous mutations that completely abolished cellular responses to both IFN-γ and IFN-α/β. Responses to IL-27 and IL-29 (IFN-λ) were abolished, potentially accounting for the susceptibility of these children to bacteria and viruses, respectively. All patients had disseminated BCG disease. One patient died from recurrent encephalitis caused by HSV, a second died from an undocumented illness thought to be of viral origin, and a third died 3 months after HSCT, from EBV-induced lymphoproliferative disorder. The principal causes of death in children with AR complete STAT1 deficiency are viral diseases or disseminated infection with BCG[38](unpublished data). The outcome of viral illnesses in children with AR complete STAT1 deficiency suggests that the STAT1-dependent response to human IFN-α/β is necessary for viral immunity. The patients with AR complete STAT-1 deficiency had multiple, severe, early-onset viral infections. Multiple antibiotics against mycobacteria and possibly antiviral treatment directed against herpes viruses should be administered without interruption, and HSCT should be considered for these patients. Vaccination with live BCG is contraindicated. Partial, as opposed to complete, AR STAT1 deficiency has also been described in three unrelated kindreds.[24] These patients suffered from mild mycobacterial and viral diseases. Their responses to IFN-γ and IFN-α were impaired, but not abolished, in terms of GAF- and ISGF3-mediated immunity. AR complete and partial STAT1 deficiencies constitute an innate immunodeficiency, ranging from lethal to moderate clinical disease, and a diagnosis of STAT1 deficiency should be considered in infants and children with infectious diseases, particularly (but not exclusively) if mycobacterial and viral in nature.[24]

GENETIC DISORDERS OF THE TLR3–IFN-α, IFN-β, AND IFN-λ PATHWAY

This group of genetic disorders leads to impaired TLR3 signaling and susceptibility to HSE in childhood. The affected patients bear mutations of *TLR3, UNC93B1, TRIF, TRAF3, TBK1,* or *IRF3* (Fig. 36.4). The TLR3 signaling pathway is mediated exclusively by the TRIF adapter and leads to activation of the transcription factors IRF3 and NF-κB (see Fig. 36.4).[39] TRIF recruits TNF receptor–associated factor 6 (TRAF6) and activates TAK1 for NF-κB activation. TRIF also recruits a signaling complex involving TBK1 and IKKε via TRAF3 for IRF3 activation.[39] This signaling pathway induces the production of type I and type III IFNs and inflammatory cytokines and is important in antiviral immunity.[39] UNC-93B is a 12-transmembrane domain protein present in the ER that delivers the nucleotide-sensing receptors TLR3, -7, -8, and -9 from the ER to endolysosomes. TRAF-3, TBK1, and IRF3 have functions downstream from multiple tumor necrosis factor (TNF) receptors and the receptors inducing IFN-α, -β, and -λ production, including TLR3.

TLR3 Deficiency

AD and AR forms of TLR3 deficiency caused by heterozygous, compound heterozygous, or homozygous mutations of *TLR3* were first identified in 2007 (OMIM 613002).[4,8] Six patients from six unrelated kindreds have been reported, and each of these patients developed childhood HSE as a result of AR or AD, complete or partial TLR3 deficiency. There is a high degree of allelic heterogeneity, with three AD partial defects resulting from negative dominance or haploinsufficiency, and two AR defects resulting from complete or partial deficiency. Some subsets of blood leukocytes (MDDCs, NK cells, and CD8 T cells) from patients with TLR3 deficiency have an impaired response to stimulation with TLR3 agonist.[8,40] The fibroblasts of the patients produce low levels of the antiviral molecules IFN-β/-λ in response to TLR3 agonist and HSV-1, leading to higher levels of viral replication and virus-induced cell death than for healthy control cells. Only one child from each of the kindreds identified developed HSE. The patients with TLR3 deficiency developed HSE upon primary infection with HSV-1 during childhood. Four (66%) of the six patients with TLR3 deficiency had at least one late relapse of HSE, whereas relapse generally occurs in only about 10% of HSE patients.[8] All patients with HSC who had TLR3 deficiency were exposed to other viruses during many years of follow-up, as shown by the positive serological results obtained for other herpes viruses, with no subsequent acute events.[8] None of the other individuals from the six kindreds with dominant or homozygous hypomorphic *TLR3* mutations developed HSE despite serologically documented HSV-1 infection.

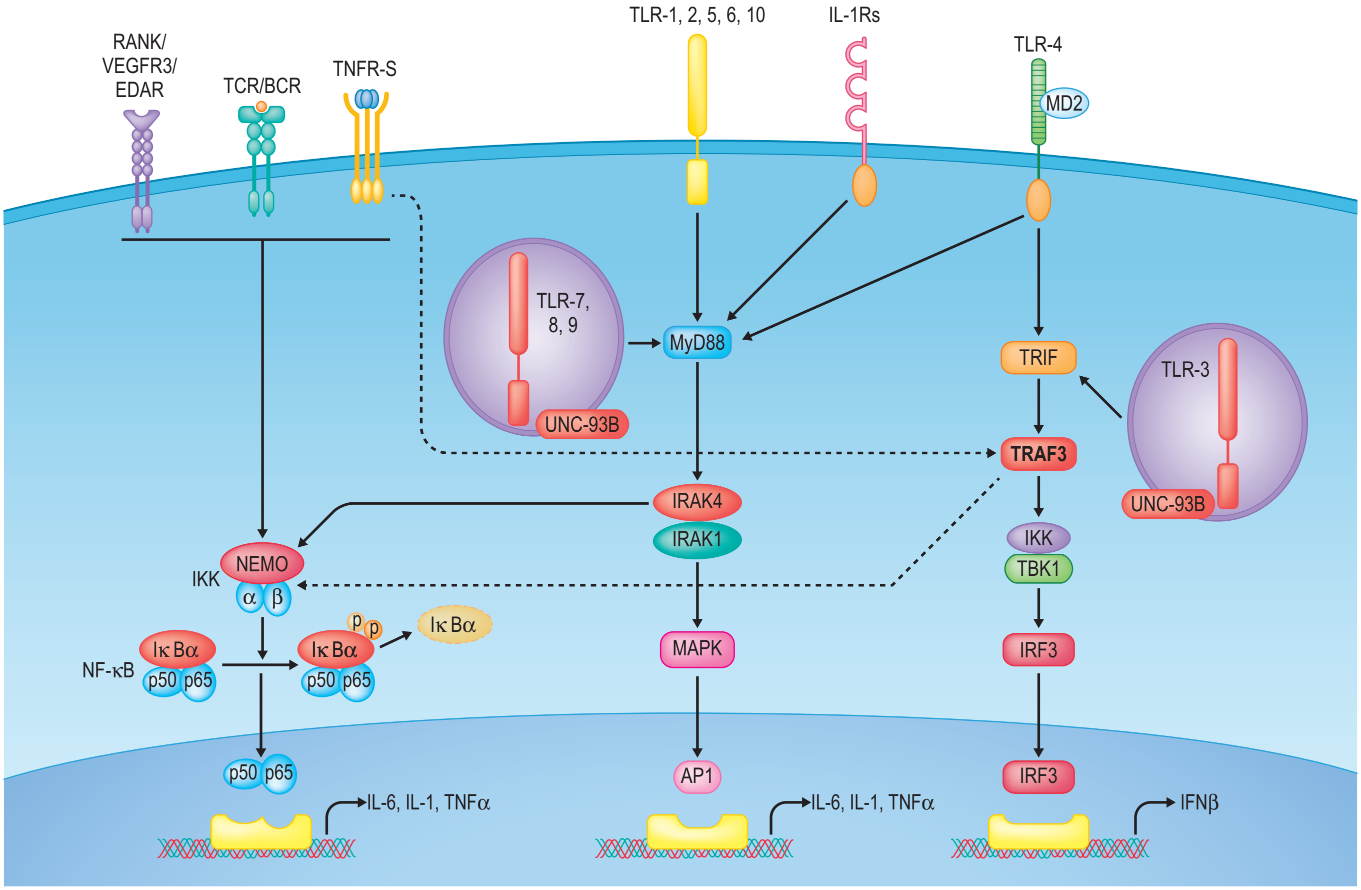

FIG 36.4 **Human Defects Involving the Interferon (IFN)-α/-β, IFN-λ and Nuclear Factor (NF)-κB Pathways.** Immune receptor signaling pathways leading to NF-κB activation can be grouped into four categories on the basis of the surface receptors involved: the developmental receptors RANK, VEGFR3, and EDAR; antigen receptors (T-cell receptor [TCR] and B-cell receptor [BCR]); members of the tumor necrosis factor (TNF) receptor superfamily (TNF-Rs) and members of the TIR superfamily (IL-1Rs/TLRs). The two proteins of the Toll/IL-1R (TIR) signaling pathway (MyD88, IRAK-4) and the two proteins of the NF-κB signaling pathway (NEMO and IκBα) responsible for primary immune deficiencies (PIDs) are shown in red. UNC-93B defects abolish cellular responses to TLR3 and 7–9 agonists. TNF receptor–associated factor 3 (TRAF3) defects impair the cellular responses to TLR3 and other pathways. The three proteins of the TLR3 signaling pathway (TLR3, UNC-93B, and TRAF3) responsible for PIDs are shown in red.

Childhood-onset HSE is, therefore, caused by TLR3 deficiency in an identifiable fraction of patients, particularly those displaying HSE recurrence. Treatment with recombinant IFN-α, in parallel with acyclovir, may help improve the outcome in patients with TLR3 deficiency and HSE. TLR3 deficiency displayed complete penetrance at the cellular level but incomplete penetrance at the clinical level. Multiple factors may affect clinical penetrance, including age at infection with HSV-1, the viral inoculum, and human modifier genes.[8]

UNC-93B Deficiency

AR complete UNC-93B deficiency was identified, in 2006, as the first genetic etiology of isolated HSE (OMIM 610551).[3] Three individuals from two consanguineous kindreds were found to carry homozygous mutations of *UNC93B1*. UNC-93B-deficient fibroblasts and leukocytes did not respond to TLR3, or to TLR7-9 agonists, respectively, in terms of IFN-α, -β, and -λ production. Fibroblasts from patients with UNC-93B deficiency displayed abnormally high levels of viral replication and cell death after infection with HSV-1.[3] Two of the three individuals with UNC-93B deficiency developed HSE. The first patient presented recurrent episodes of HSE at the ages of 11 months, 14 months, and 3½ years. During 14 years of follow-up, this patient has experienced no subsequent acute events. The second patient presented recurrent episodes of HSE at the ages of 5 and 17 years. She is now 21 years old, and her clinical status has not worsened since the second episode of HSE. One sibling of the second patient, who carries the same homozygous mutation in *UNC93B1,* is now 30 years old and has not developed HSE, despite serologically documented HSV-1 infection. The two patients with UNC-93B deficiency and HSE have been exposed to other viruses with no evident clinical manifestations.[3] Treatment with recombinant IFN-α may also be considered, in parallel with acyclovir, in patients with UNC-93B deficiency and HSE.

TRIF Deficiency

The subsequent discovery of AR and AD TRIF deficiencies in children with HSE completely validated the essential role of human TLR3 immunity in anti-HSV-1 defense in the central nervous system (CNS).[7] A patient with AR TRIF deficiency, born to consanguineous Saudi parents, suffered from HSE at the age of 2 years. A homozygous nonsense mutation, R141X, was identified as the cause of her AR TRIF deficiency.[7] Another patient, with AD TRIF deficiency, of mixed European descent (French, Portuguese, and Swiss), suffered from HSE at the age of 21 months. A heterozygous missense mutation, S186L, led to AD TRIF deficiency in this girl.[7]. The two patients with TRIF deficiency have displayed no other unusually severe infectious diseases during follow-up to date. The TLR3 signaling pathway was found to be impaired in cells from patients with both AR and AD TRIF deficiencies, whereas the TRIF-dependent TLR4 pathway was affected only in patients with AR TRIF deficiency. Interestingly, abnormally weak responses to stimulation of the DExD/H-box helicase pathway have been observed in both AR and AD TRIF-deficient fibroblasts. These results demonstrate the importance of TRIF for the TLR3-dependent production of antiviral IFNs in the CNS during primary infection with HSV-1.[7] However, they also suggest that the TRIF-dependent TLR4 and, probably, the DExD/H-box helicase pathways, are largely redundant in host defense in humans.

TRAF3 Deficiency

A French patient with AD TRAF3 deficiency and HSE has recently been identified.[5] The *de novo* germline heterozygous missense mutation in this patient is loss-of-expression, loss-of-function, and dominant-negative. Fibroblasts from the patient displayed impaired responses to TLR3 agonist stimulation, in terms of IFN-β and -λ production. Various TRAF3-dependent pathways were impaired in the patient's cells, including the IFN-α/β-, and IFN-λ–inducing and TNF-R–responsive pathways. However, there was sufficient residual TRAF3-dependent signaling for most defects to remain clinically silent. By contrast, the impaired TLR3 response was symptomatic and caused HSE, implying that the TLR3 pathway is critically dependent on TRAF3 and essential for immunity to HSV-1 in the CNS. The first clinical signs of HSE in the patient with TRAF3 deficiency appeared at the age of 4 years. The patient with TRAF3 deficiency and HSE described here is now 18 years old and has otherwise remained healthy with no prophylaxis.[5] She shows normal resistance to other infectious diseases, including viral diseases, in particular.[5] We cannot yet exclude the possibility that other forms of human TRAF3 deficiency are involved in other human diseases, including viral diseases, but TRAF3 deficiency should be sought in other children with HSE.

TBK1 Deficiency

The identification of AD TBK1 deficiency as a new genetic etiology of isolated childhood HSE was probably the greatest surprise to come out of human studies to date.[6] TBK1 is a kinase at the crossroads of multiple IFN-inducing signaling pathways, including those mediated by TLR3, cytosolic double-stranded RNA (dsRNA) sensors, and dsDNA sensors. Two unrelated children with HSE were found to carry different heterozygous missense mutations in the gene encoding TBK1. Both mutations underlie a phenotype that is dominant, but presumably by different mechanisms: negative dominance (G159A) and haplotype insufficiency (D50A). A defect in poly(I:C)–induced TLR3 responses was detected only in fibroblasts from the patient carrying the dominant-negative *TBK1* mutation.[6] Nevertheless, levels of viral replication and cell death caused by two TLR3-dependent viruses (HSV-1 and VSV) were high in fibroblasts from both patients. However, the peripheral blood mononuclear cells (PBMCs) and fibroblasts from both patients displayed normal IFN responses to the TLR3-independent agonists and viruses tested.[6] AD TBK1 deficiency, therefore, confers narrow, partial cellular phenotypes, probably accounting for the narrow clinical phenotype of these patients, which is limited to HSE. The two patients with TBK1 deficiency suffered from HSE at the ages of 7 years and 11 months, respectively. During subsequent follow-up over a period of years, they have suffered no other unusual infectious diseases, including viral diseases, in the absence of prophylaxis. As in other HSE patients with genetic deficiencies of the TLR3 pathway, treatment with recombinant IFN-α, in parallel with acyclovir, may be considered in patients with TBK1 deficiency and HSE.

IRF3 Deficiency

IRF3 is a transcription factor that controls multiple IFN-inducing pathways, including the TLR3 pathway, which can be triggered by dsRNA, and the pathways triggered by other RNA and DNA sensors. IRF3 is normally activated by TBK1 and/or IKKε kinases. A missense IRF3 mutation has been identified in a 15-year-old patient with HSE.[9] The resulting mutant IRF3 protein could not activate transcription and was dominant through haploinsufficiency. In heterozygous cells, haploinsufficiency for IRF3 impairs the induction of antiviral IFN-α/β in leukocytes following stimulation with various agonists. Moreover, the induction of IFN-β in fibroblasts stimulated with poly(I:C), which mimics viral dsRNA and activates TLR3, was also impaired. Finally, IFN-β induction by HSV1 was impaired in fibroblasts. Overall, consistent with the key role of IRF3 in inducing IFN-α/β, a profound, broad cellular phenotype was observed in patients with AD IRF3 deficiency. Despite the broad impact of AD IRF3 deficiency, in terms of both the pathways and cell types affected, its clinical phenotype in the single patient identified to date is surprisingly narrow, restricted to HSE.[9] Moreover, clinical penetrance is incomplete, as a heterozygous relative of the patient is healthy. Overall, the discovery of IRF3 deficiency in a patient with HSE suggests that IRF3 is a key component in TLR3-dependent, IFN-mediated, CNS-intrinsic immunity to HSV-1. It also adds weight to the emerging notion that impaired TLR3-IFN immunity can underlie HSE of childhood, suggesting that IFN treatment may be beneficial to patients.[9]

IRF7 Deficiency

AR complete IRF7 deficiency was identified, in 2015, as the first genetic etiology of severe isolated influenza (OMIM 616345).[10] A 30-month-old girl born to nonconsanguineous French parents was admitted to intensive care for 3 weeks and required respiratory support for 10 days because of pandemic H1N1 (pH1N1) 2009 influenza A virus (IAV)–induced acute respiratory distress syndrome. This patient carries compound heterozygous mutations, p.F410V and p.Q421X, in *IRF7,* encoding IRF7.[10] Each of her parents has a single heterozygous mutation, and neither has any significant infectious disease history. IRF7 is required for the production and amplification of the antiviral type I (IFN-α/β) and III (IFN-λ) IFNs. The patient's fibroblasts displayed impaired IFN-β and IFN-λ1 production in response to various stimuli, including IAV. Consequently, IAV replication resulted in titers 100 times higher in the patient's fibroblasts than in fibroblasts from a healthy donor. Furthermore, type I IFN production was abolished in the patient's plasmacytoid DCs, a cell type that normally produces constitutively high levels of IRF7 and, therefore, large amounts of type I IFN. Moreover, pulmonary epithelial cells differentiated *in vitro* from patient-specific induced pluripotent stem cells displayed uncontrolled virus replication and impaired IFN-β production. The patient had no other serious viral infections despite being seropositive for a myriad respiratory viruses and is currently healthy at the age of 8 years.[10] Thus the IRF7-dependent IFN amplification pathway is crucial for the mounting of antiviral responses to influenza virus but may be redundant for other viruses.

GENETIC DISORDERS OF NF-κB–MEDIATED IMMUNITY

This group of inherited disorders leads to impaired NF-κB signaling and strong susceptibility to pyogenic bacteria. Affected patients bear mutations of *NEMO, NFKBIA, IRAK4, MYD88, HOIL1,* or *HOIP* (see Fig. 36.4).[16,41,42] Patients with ectodermal dysplasia, anhidrotic (EDA) and immunodeficiency (EDA-ID) syndrome carry either XR hypomorphic mutations of *NEMO,* AD hypermorphic mutations of *NFKBIA*, or AR amorphic mutations of *IKKB.*[43] Diverse mutations have been found in *NEMO,* associated with various cellular and clinical phenotypes (see above and below).[44] Patients with AR amorphic mutations of *IRAK4* or *MyD88* present a more restricted, purely immunological defect, with specific impairment of the TIR-IL receptor–associated kinase (IRAK) signaling pathway.[13] Patients with NEMO, IκBα, IKKB, HOIL1, or HOIP deficiencies are susceptible to multiple infectious agents, including pyogenic bacteria, mycobacteria, and viruses. By contrast, patients with IRAK-4 or MyD88 deficiencies seem to be specifically prone to pyogenic bacterial diseases.

NEMO Deficiency

XR-EDA-ID is a rare PID associated with a developmental disorder (OMIM 300291). Patients with XR-EDA-ID carry hypomorphic mutations of *IKBKG,* which encodes IKK-γ/NEMO, a protein essential for activation of the ubiquitous transcription factor NF-κB. Up to 100 patients with NEMO deficiency have been reported.[16,43] The only known consistent immunological abnormality in patients with NEMO deficiency is an absence of serum antibodies against carbohydrates, which has been found in most of the patients described to date. Some patients have hyper-IgM syndrome, and a few have NK-cell abnormalities. Most patients with NEMO deficiency fail to produce IL-10 in response to activation with TNF-α in whole-blood assays.[16]

The infectious phenotype of the other NEMO-deficient patients is characterized mostly by infections caused by encapsulated pyogenic bacteria, such as *H. influenzae* and *Streptococcus pneumoniae.* Infections caused by weakly pathogenic microorganisms, such as *M. avium* and *M. kansasii,* have also been diagnosed in patients.[16] Other infectious diseases, including salmonellosis, *Pneumocystis* pneumonia, and viral illnesses caused by HSV and CMV, have been reported. Infectious episodes were marked by a poor clinical and biological inflammatory response.[44] One-third of the patients with NEMO deficiency died from invasive infection, demonstrating the severity of this disorder.[44] About 80% of the patients with NEMO deficiency described to date have had EDA-ID, which is characterized by hypohidrosis, widely spaced cone-shaped or peg-shaped teeth, and hypotrichosis[16] (Fig. 36.5). These features result from defective signaling via the ectodysplasin receptor signaling pathway. In some other patients with NEMO deficiency, osteopetrosis (O) and lymphedema (L) have been found associated with the EDA phenotype.[16] Some patients also have dysmorphia with mild frontal bossing. However, about 10% of patients with NEMO deficiency do not display any of the classic features of the EDA phenotype.[16]

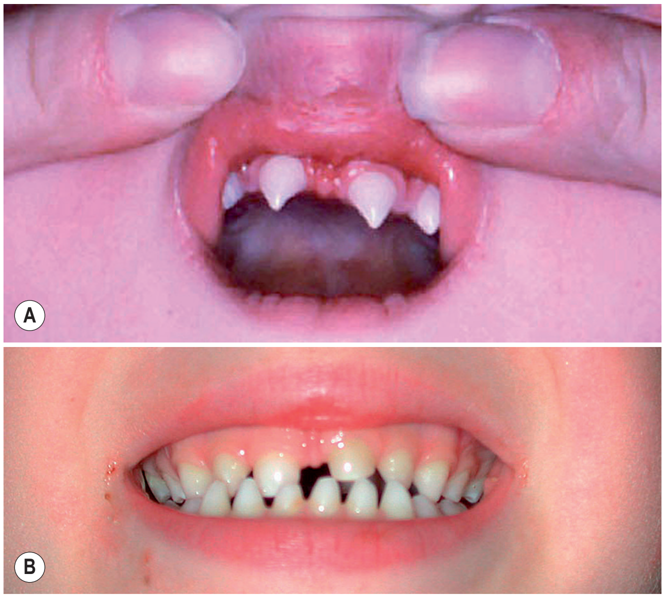

FIG 36.5 Patients With Anhidrotic Ectodermal Dysplasia and Immunodeficiency (EDA-ID). Two patients with EDA-ID, one with widely spaced cone- or peg-shaped teeth (A), the other having conical incisors (B).

Prophylactic trimethoprim–sulfamethoxazole and/or penicillin V treatment should be considered and IgG substitution should be carried out in patients with NEMO deficiency presenting an impairment of B-cell immunity. Patients with functional B-cell immunity should be immunized with *S. pneumoniae* conjugated and nonconjugated vaccines, *H. influenzae* conjugated vaccine, and *N. meningitidis* conjugated and nonconjugated vaccines. Vaccination with live BCG is contraindicated. It is important to initiate empiric parenteral antibiotic treatment against *S. pneumoniae, Staphylococcus aureus, Pseudomonas aeruginosa,* and *H. influenzae* as soon as infection is suspected or the patient develops a moderate fever, without taking inflammatory parameters into account, as patients may die of rapid invasive bacterial infection despite appropriate prophylaxis. HSCT should be considered for patients with severe infectious and cellular phenotypes[16] (Picard unpublished).

IκBα Deficiency

Ten patients with three different hypermorphic mutations of *NFKBIA,* which encodes an inhibitor of NF-κB (OMIM 164008), have been identified since 2003, one of whom displays complex partial mosaicism.[15,16] IκBα deficiency can lead to an impairment of T-cell receptor (TCR) signaling in 70% of patients, and all have impaired TNF receptor (TNFR) and IL1R/TLR responses. Patients with IκBα deficiency have dysgammaglobulinemia and impaired production of specific antibodies. Some also have low proportions of memory CD4 or CD8 T cells or both, excess naïve T cells, or an absence of TCRγ/δ T cells. With the exception of two patients with IκBα deficiency, one with complex mosaicism and one with S36Y mutation, all patients have been found to have the features of EDA.[16] All 10 patients with IκBα deficiency have developed recurrent bacterial infections: pneumonia in five cases, sepsis or meningitis in three cases, and arthritis in one case. They are also prone to opportunistic infections, six of these patients having had *Pneumocystis* pneumonia and CMC. Finally, some patients presented with recurrent diarrhea and/or colitis. Thus a diagnosis of IκBα deficiency should be considered in children with EDA and CID with impaired T-cell immunity. A preventive treatment, including antibiotic prophylaxis with trimethoprim–sulfamethoxazole and/or penicillin V, should be proposed and IgG substitution should be carried out in patients with IκBα deficiency. The recommendations for febrile patients with NEMO deficiency should also be applied to patients with IκBα deficiency. HSCT has been reported in four patients with severe IκBα deficiency causing CID.[45,46]

IL-1 Receptor–Associated Kinase-4 Deficiency

Inherited IRAK-4 deficiency (OMIM 607676) is an AR disorder first described in 2003.[11] In total, 49 patients have since been identified, from 32 kindreds.[13,16] The blood cells of the patients fail to produce the proinflammatory cytokines IL-1β and IL-18 upon stimulation with all known TLR agonists (with the exception of TLR3 agonists). Patients with IRAK-4 deficiency seem to have normal antigen-specific T- and B-cell responses, as shown in routine immunological investigations, with two notable exceptions.[47] First, the glycan-specific IgG and IgM antibody responses to pneumococcal and AB glycans (allohemagglutinins of the ABO system) are impaired in up to one-third of the cases explored.[13] Second, serum IgE and IgG4 concentrations are high in up to two-thirds and one-third, respectively, of patients tested.[13]

THERAPEUTIC PRINCIPLES

Patients with Inherited Disorders of Toll and IL-1 Receptor (TIR)-Mediated Immunity

- Patients should receive conjugated and nonconjugated vaccines against encapsulated bacteria (*Pneumococcus, H. influenzae, Meningococcus*).
- A preventive treatment, including antibiotic prophylaxis with cotrimoxazole plus penicillin V, should be administered throughout the life of the patient.
- Monthly prophylactic administrations of intravenous or subcutaneous immunoglobulins should be considered in selected patients.
- Empiric parenteral antibiotic treatment against *Streptococcus pneumoniae, Staphylococcus aureus,* and *Pseudomonas aeruginosa* should be initiated as soon as an infection is suspected or if the patient develops a moderate fever, without taking inflammatory parameters into account.
- Hemopoietic stem cell transplantation (HSCT) should be considered in selected patients with NEMO and IκBαα deficiency.

IRAK-4–deficient patients suffer from recurrent infections caused by pyogenic bacteria, mostly *S. pneumoniae, S. aureus,* and *P. aeruginosa,* with little or no fever or inflammatory response.[13] The leading pathogen responsible for infections in these patients is *S. pneumoniae,* which was found in half the cases of documented invasive infection (septicemia, meningitis, abscesses, or arthritis), whereas *S. aureus* and *P. aeruginosa* were found in 14% and 19% of such episodes, respectively. Patients with IRAK-4 deficiency also suffer from noninvasive pyogenic bacterial infections, mostly affecting skin and upper respiratory tract, with necrotizing infections particularly common. The principal bacterial strains isolated during noninvasive infections in patients with IRAK-4 deficiency are *S. aureus* in 43% of episodes, *P. aeruginosa* in 22% of episodes, and *S. pneumonia* in 16% of episodes. All reported sudden invasive infections occurred before the age of 14 years. IRAK-4 deficiency is a life-threatening disease, resulting in the deaths of 20 of the 49 known patients, all of whom died before the age of 8 years. Eleven of these patients died from invasive pneumococcal disease. There is an overall trend toward improvement with age, as shown by the seven adult patients doing well with no treatment at ages of 18 to 37 years.

Patients with IRAK-4 deficiency should also be immunized with *S. pneumonia, H. influenzae, N. meningitidis* conjugated vaccine (and also nonconjugated vaccine when available). A preventive treatment, including antibiotic prophylaxis with cotrimoxazole plus penicillin V, should be administered throughout the life of the patient. Given the severity of bacterial infection during childhood and the defective antibody production found in some patients with IRAK-4 deficiency, we also recommend the administration of empiric IgG replacement until the patient is at least 10 years old. This prophylaxis seems to decrease the incidence of invasive bacterial infections.[13] It is important to initiate empiric parenteral antibiotic treatment against *S. pneumoniae, S. aureus,* and *P. aeruginosa* as soon as an infection is suspected or if the patient develops a moderate fever, without taking inflammatory parameters into account because patients may die of rapid invasive bacterial infection despite appropriate prophylaxis. A diagnosis of IRAK-4 deficiency should be considered in children presenting with recurrent pyogenic infection and poor inflammatory responses.

MYD88 Deficiency

MyD88 deficiency is an AR disorder recently described in 22 patients (OMIM 612260).[12,13,16] Patients with MyD88 deficiency display a lack of production of IL-6 by whole blood and no CD62L shedding from granulocytes following activation with most of the TLR and IL-1R agonists tested, with the exception of TLR3, which signals through a MyD88-independent pathway.[12] Thus there seems to be no overt defect of leukocyte development in patients with MyD88 deficiency, and antigen-specific T- and B-cell responses appear to be normal, as shown by routine immunological analyses, in most cases.[16] Serum IgE and IgG4 concentrations were high in up to one-half and one-third, respectively, of the patients tested.[13] Some of the modest, subclinical abnormalities of B-cell responses observed, such as the production of low levels of antibodies against carbohydrates in some patients, may thus reflect impaired TACI responses, rather than impaired TLR and IL-1R responses. MyD88 deficiency, like IRAK-4 deficiency, confers a predisposition to severe bacterial infection, with impairment of the ability to increase plasma C-reactive protein (CRP) concentrations and to mount fever at the beginning of infection. However, pus formation has been observed at various sites of infection.

Patients with MyD88 deficiency present a narrow susceptibility to invasive pyogenic bacterial infections.[16] *S. pneumoniae* was involved in 41% of the documented invasive episodes in patients with MyD88 deficiency, whereas *S. aureus* and *P. aeruginosa* were found in 20% and 16% of such episodes, respectively. Most patients with MyD88 deficiency suffered from their first bacterial infection before the age of 2 years. Nine patients died from invasive bacterial infections, all before the age of 4 years, and most before the age of 1 year.[16] Seven of these patients died from invasive pneumococcal disease. However, MyD88 deficiency seems to improve with age, and none of the patients has presented invasive bacterial infection after adolescence.[13] MyD88 deficiency also confers a predisposition to noninvasive pyogenic bacterial infections, mostly affecting skin and the upper respiratory tract. The principal bacterial strains found during noninvasive infections were *S. aureus* in 53% of patients, *S. pneumoniae* in 20% of patients, and *P. aeruginosa* in 13% of patients. Most patients with MyD88 deficiency have had noninvasive bacterial infections, with half of the patients suffering from their first noninvasive bacterial infection before the age of 2 years. Patients with MyD88 deficiency continue to suffer from skin infections, sinusitis, or pneumonia, even after reaching adolescence. Treatment recommendations for patients with MyD88 deficiency are identical to those for those with IRAK-4 deficiency (see above). A diagnosis of MyD88 deficiency should be considered in children presenting with recurrent pyogenic infection with poor inflammatory responses.

THERAPEUTIC PRINCIPLES

Treatment of Patients with HSE Susceptibility

- Treatment with interferon (IFN)-α, in parallel with acyclovir, may help to improve disease outcome in patients with Toll-like receptor 3 (TLR3) pathway deficiencies, in particular.
- Serological monitoring for herpes simplex virus 1 (HSV-1) infection should be considered in individuals carrying mutations of TLR3 pathway genes but with no anti-HSV-1 antibody detectable in serum.
- In the absence of an effective vaccine against HSV-1, acyclovir may be considered an appropriate prophylactic treatment in individuals carrying mutations of TLR3 pathway genes, even if serologically negative for HSV-1.

HOIL1 Deficiency

The linear ubiquitination chain assembly complex (LUBAC) is assembled by a complex containing HOIL1 (also known as RBCK1), SHARPIN, and HOIP (also known as RNF31). LUBAC adds head-to-tail linear polyubiquitin chains to substrate protein and has been implicated in NF-κB signaling, together with NEMO, RIPK1, and ASC1. AR *HOIL1* (*HOIL1*/*RBCK1,* OMIM# 610924) deficiency, caused by homozygous or compound heterozygous mutations of the *HOIL1* gene, has been identified in three patients. These patients had a paradoxical clinical phenotype combining an autoinflammatory syndrome with pyogenic bacterial diseases, which led to their death.[41] LUBAC deficiency results in an impaired response to TNF and IL-1β in fibroblasts or to CD40L in B cells, but hyperresponsiveness to IL-1β in monocytes. All three patients had recurrent systemic inflammatory symptoms, present from the first few months of life, as a result of monocyte overactivation. They also developed recurrent pyogenic bacterial infections caused by *S. pneumoniae, H. influenzae, Escherichia coli, Staphylococcus* spp., and *Enterococcus,* partly because of their inability to produce antipolysaccharide antibodies. One patient also had chronic CMV infection and another had *Giardia intestinalis* infection.[41] All three patients also had amyotrophy, muscle weakness, and failure to thrive, partly as a result of muscular amylopectinosis complicated by myopathy and cardiomyopathy.[41] More recently, 14 patients with HOIL1 deficiency from 10 unrelated kindreds have been reported, with identification on the basis of neuromuscular and cardiac involvement secondary to amylopectinosis. Patients with HOIL1 deficiency should be immunized (with *S. pneumoniae* conjugated and nonconjugated vaccines, *H. influenzae* conjugated vaccine, and *N. meningitidis* conjugated and nonconjugated vaccines). Prophylactic penicillin V treatment and IgG substitution should also be considered. Heart transplantation should be considered for patients with heart failure. The autoinflammation is more difficult to control. One patient underwent HSCT, which corrected the autoinflammation and the predisposition to infectious disease.

HOIP Deficiency

AR *HOIP* (*HOIP* is also known as *RNF31,* OMIM 612487) deficiency caused by a homozygous mutation has also been identified in one patient. This patient displayed an autoinflammatory syndrome, pyogenic bacterial diseases, amylopectinosis, and lymphangiectasia.[42] At the cellular level, HOIP deficiency causes the same impaired responses to TNF and IL-1β agonists found in patients with AR HOIL-1 deficiency. Systemic inflammation results from the overactivation of monocytes in response to stimulation with IL-1β. Immunological investigations showed T-cell lymphopenia, an impaired proliferative response to anti-CD3, and hypogammaglobulinemia associated with nonprotective antibody responses to *S. pneumoniae* and *H. influenzae,* but with a good antibody response to tetanus toxoid. In addition to recurrent autoinflammation, this patient developed generalized lymphadenopathy after immunization with BCG. She also had recurrent episodes of diarrhea, amyotrophy, muscle weakness, and failure to thrive,[42] partly because of muscle amylopectinosis. Patients with HOIP deficiency should be treated in the same way as those with HOIL-1 deficiency.

GENETIC DISORDERS OF TH17-MEDIATED IMMUNITY

CMC is characterized by persistent or recurrent infections of skin (intertrigo, angular cheilitis), mucous membranes (oral, esophageal, genital), and nails (onychomycosis) caused by *Candida* (*C. albicans* in particular).[48] CMC was first described in the 1960s and was reported to display AD heritance. Isolated CMC usually begins early in infancy and affects otherwise healthy individuals. Invasive candidiasis, dermatophytosis, bacterial infections of the respiratory tract, and cutaneous infections caused by *Staphylococcus* have been reported in some patients. In rare cases, an association with cerebral aneurysm or oral/esophageal squamous cell carcinoma, and thyroid autoimmunity has also been described. These PIDs are caused by mutations of the *IL17RA, IL17RC, IL17F, ACT1,* and *STAT1* genes (Fig. 36.6).[17-20] Some patients with invasive candidiasis carry mutations of the *CARD9* gene.[49] The molecular and clinical features of CMC have been reviewed elsewhere. In particular, this condition is reported in patients with AR autoimmune polyendocrinopathy syndrome type 1 (APS-1 or APECED) (OMIM 240300). APS-1 is caused by mutations of the *AIRE* gene resulting in impaired T-cell tolerance, with 88% of patients developing CMC. High levels of neutralizing autoantibodies against IL-17A, IL-17F, and/or IL-22 have been detected in the serum of patients with APS-1.[50]

AR complete IL-17RA deficiency (OMIM 613953) was first identified in 2011 (see Fig. 36.6). A patient from a consanguineous family from Morocco was found to suffer from recurrent CMC (resistant to local antifungal treatment), cutaneous abscesses and folliculitis caused by *S. aureus,* acute otitis media, and lower respiratory tract infections.[17] No invasive bacterial infectious disease was reported in this patient. A homozygous premature stop codon was found to prevent production of the protein in this patient. The cellular phenotype was characterized by an absence of response to IL-17A and IL-17F homo- and heterodimers and to IL-17E (IL-25), in the patient's fibroblasts.[17] Seventeen other patients from nine unrelated kindreds have since been identified (Puel A).

AD IL-17F deficiency (OMIM 613956) was also first described in 2011 (see Fig. 36.6).[17] Patients from a multiplex kindred from

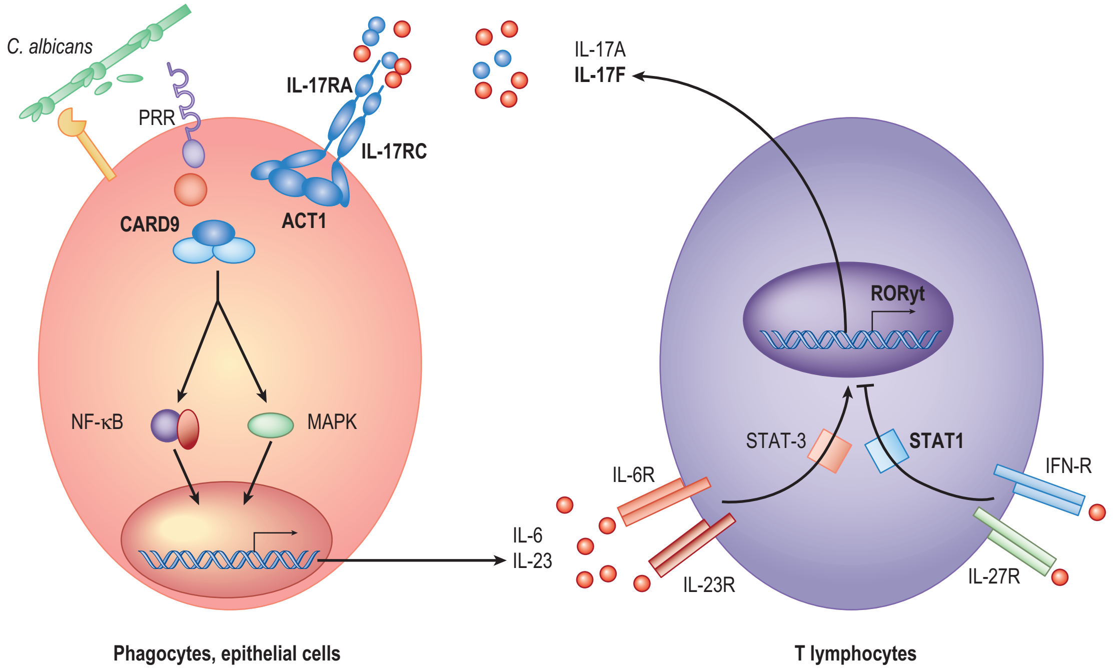

FIG 36.6 Genetic Etiologies Affecting the Interleukin (IL)-17 Pathway. Schematic representation of IL-17 immunity and cooperation between cells recognizing *Candida albicans* (phagocytes and epithelial cells) and cells producing IL-17 cytokines (T and innate [NK] lymphocytes). CMCD-causing mutations (in blue) of IL-17F, IL-17RA, IL17RC, CARD9, and ACT1 impair IL-17 function or response. CMCD-causing gain-of-function mutations (also shown in blue) in *STAT1* impair the development of IL-17–producing T cells.

Argentina displayed isolated CMC (see Fig. 36.6). A monoallelic mutation of *IL17F* was detected and found to have no impact on protein production. However, this mutation greatly decreased the activity of homo- and heterodimers (IL-17F/IL-17F or IL-17A/IL-17F) by affecting binding of the complex to the receptor. Another patient with a monoallelic mutation of *IL-17F* has been reported, but no cellular characterization was carried out.[17]

AR complete IL-17RC deficiency has been reported in three unrelated patients from Turkey and Argentina.[18] All patients suffered from CMC, and none presented invasive or recurrent bacterial infections. The clinical manifestations of infectious diseases in this group of patients resembled those in patients with AD IL-17 deficiency.[18] The three homozygous mutations identified, Q138X, R376X and R378X, confer a loss of IL-17RC protein expression in transfected HEK293T cells, with complete abolition of the response to IL-17A and IL-17 homo- and heterodimers.[18]

Genome-wide approaches led to the discovery of heterozygous *STAT1* missense mutations in patients with CMC disease (D) (OMIM 614162).[20] These mutations, unlike the previously reported mono- or biallelic *STAT1* loss-of-function mutations associated with susceptibility to mycobacterial, intracellular bacterial, and viral infections, were shown to be gain of function (GOF).[24] A recent study from the International STAT GOF group described 274 patients from 167 kindreds from 40 countries on five continents.[20] In total, 76 mutations of the *STAT1* gene have been identified and characterized *in vitro*. CMCD-causing *STAT1* mutations enhance the responses of STAT1 to IFN-α/β, IFN-γ, and IL-27 and of the repressors of IL-17 T-cell development, probably accounting for the low IL-17 T-cell counts in these patients, resulting in CMCD.[20] In AR APS-1 (APECED;)(OMIM 240300), caused by autoimmune regulator (AIRE) deficiency and resulting in impaired T-cell tolerance, 88% of patients develop CMC. High levels of neutralizing autoantibodies against IL-17A, IL-17F, and/or IL-22 have been detected in the serum of patients with APS-1.[50]

AR complete ACT1 deficiency has been reported in two patients from a consanguineous family from Algeria.[19] These two siblings developed CMC. However, one of them presented recurrent episodes of folliculitis decalvans and bilateral blepharitis caused by *S. aureus*. Their cellular phenotypes are characterized by impaired responses to IL-17A and IL-17F in fibroblasts and impaired responses to IL-17E in T lymphocytes.[19]

THERAPEUTIC PRINCIPLES

Treatment of Chronic Mucocutaneous Candidiasis (CMC)

- A preventive antifungal treatment, (principally fluconazole) should be administered in the long term, followed by other antifungal drugs, such as itraconazole or posaconazole.
- Antibiotic prophylaxis should be considered in selected patients with cutaneous staphylococcal disease.
- Monthly prophylactic administration of intravenous immunoglobulin should be considered in selected patients with recurrent pneumonia.
- Granulocyte–colony-stimulating factor (G-CSF), the JAK inhibitor ruxolitinib, or hemopoietic stem cell transplantation (HSCT) may also be considered.

AR complete ROR-γ/ROR-γT RORC deficiency has recently been identified in three unrelated consanguineous families from Israel, Chile, and Saudi Arabia.[51] RORC is a DNA-binding transcription factor that plays an important role in thymopoiesis. The patients suffered from an unusual combination of BCGosis and mild CMC in the absence of other clinical manifestations.[51] The three homozygous mutations identified, S38L, Q329X, and Q441X, affect both IL-17 and IFN-γ immunity. As predicted by studies in mice, the lack of functional ROR-γT protein prevents the development of IL-17-producing T cells, accounting for the chronic candidiasis observed in these patients. Surprisingly, the patients also lacked mucosal-associated invariant T (MAIT) cells and invariant natural killer T cells (iNKT), which normally produce IFN-γ and can inhibit intracellular mycobacterial replication. Moreover, their conventional CD8 α/β and γ/δ T cells, unlike their CD4 α/β T and NK cells, produced only very small amounts of IFN-γ. ROR-γ/ROR-γT thus plays a critical role in MAIT and iNKT development, and in the capacity of CD8 and γ/δ T cells to make IFN-γ. This results in a profound impairment of IFN-γ production by lymphocytes, leading to susceptibility to mycobacterial disease.[51] Antibiotic treatment can be combined with IFN-γ injection in cases of disseminated infection. The vaccination of these patients with live BCG is contraindicated.

Overall, these studies strongly suggest that IL-17 immunity plays a crucial role in defense against CMC in humans. The careful clinical description of a large series of patients would be required to determine the role of these cytokines more precisely.

CONCLUSIONS

ON THE HORIZON

- Unexplained infectious diseases occur in patients, in children in particular, as a result of an inborn error of immunity.
- Patients with severe infectious disease should be repeatedly investigated even if all standard immunological explorations are normal.
- The exploration of these defects, by application of powerful next-generation deep-sequencing technologies, provides tools for molecular diagnosis and genetic counseling and opens up exciting new perspectives benefiting patients.
- The identification of these defects will also guide rational treatment based on improvements in our understanding of these diseases' pathogenesis.

An understanding of the molecular basis of these PIDs affecting the innate immune responses mediated by IFN-γ, IFN-α/β/λ, IL-17, TIRs, or NF-κB has provided detailed insight into the pathogenesis of infections in affected patients, paving the way for genetic counseling and rational treatment design.[52] These PIDs should be sought in patients with unexplained infectious diseases, whether caused by a single or multiple infectious agents, even if all standard immunological explorations are normal.[53] Interestingly, even common infectious diseases, such as TB, invasive pneumococcal disease, and HSE may be favored by mendelian immune disorders. The discovery of many new PIDs opens up exciting new perspectives, not only increasing our understanding of immunity to pathogens but also benefiting patients. It is thought that most children with severe infectious diseases probably suffer from an underlying PID, and they should, therefore, be repeatedly investigated for known and unknown immunodeficiency conditions.

ACKNOWLEDGMENTS

We thank our laboratory colleagues, our collaborators at Necker Hospital for Sick Children and elsewhere, and patients and families for their assistance in making possible the studies contained in this chapter. We thank all the members of the Human Genetics of Infectious Diseases Laboratory for helpful discussions. The Laboratory of Human Genetics of Infectious Diseases is supported by grants from the Rockefeller University Center for Clinical and the Rockefeller University. The Laboratory of Human Genetics of Infectious Diseases is supported by the March of Dimes, the ANR, the INSERM, the FRM, and the PHRC.

MULTIPLE-CHOICE QUESTIONS

1. A 2-year-old patient was diagnosed of disseminated osteomyelitis caused by atypical mycobacteria. Immunophenotyping of T, B, and natural killer (NK) cells are normal. Respiratory burst excludes chronic granulomatous disease. What is the correct procedure in the investigation?
   A. Mitogen-induced T-cell proliferation
   B. Test of interferon (IFN)-γ pathway and treatment with multiple antimycobacterial antibiotics.
   C. Observation for 2 weeks while performing an evaluation

2. A 3-year-old boy was diagnosed of herpes simplex encephalitis, but no cutaneous lesion of herpes virus infection was observed. Immunophenotyping of lymphocytes was normal. To investigate the causal immune defect, what would be the best study to undertake?
   A. Observation during 1 week while treating with antibiotics. Acyclovir should be used if no sign of clinical recover.
   B. Test Toll-like receptors (TLR) response to multiple ligands using peripheral blood mononuclear cells.
   C. Test TLR3 responsiveness using dermal fibroblasts.

3. Patients with defect in interleukin-17 (IL-17) immunity are characterized by which of the following infectious phenotype?
   A. Patients present with persistent mucocutaneous candidiasis
   B. Patients present susceptibility to herpes virus
   C. Patients present with recurrent bacterial pneumonia

Infections in the Immunocompromised Host

Alexandra F. Freeman, Jennifer M. Cuellar-Rodriguez

As a result of improvements in antimicrobials and immunosuppressant agents, there are increasing numbers of hosts with immune deficiencies, either acquired primarily through genetic defects or acquired secondarily, for example, through treatment for malignancy and autoimmune disease, or after solid or hematopoietic stem cell transplantation (HSCT). Understanding both the genetic defects and the immunological targets of immunosuppressant agents will help further the knowledge of host control of infection. In this chapter, we review the infection spectrum of some of the major classes of primary immunodeficiencies, as well as acquired immunodeficiency, opportunistic infections in patients with human immunodeficiency virus (HIV) and acquired immunodeficiency syndrome (AIDS) are described separately in Chapter 39.

PRIMARY IMMUNODEFICIENCIES

Phagocyte Defects (Chapter 22)

Phagocytic neutrophils and monocytes are key members of the primary immune response. Neutrophils are essential in the initial host defense against microbes. Antimicrobial peptides, cytokines, and chemokines released at the site of microbial entry cause neutrophils to migrate to the site of inflammation (chemotaxis), ingest, and then kill the microbe through oxygen-dependent or oxygen-independent mechanisms. Defects in quantity or quality of neutrophils can predispose to infection, which is primarily with fungi and bacteria (Table 37.1). Defects in monocytes are less frequent and contribute to control of intracellular bacteria, mycobacteria, and fungi.

Chronic Granulomatous Disease

Chronic granulomatous disease (CGD) causes the most common qualitative neutrophil immunodeficiency. Defects in the nicotinamide adenine dinucleotide phosphate (NADPH) oxidase cause an abnormal neutrophil respiratory burst, leading to recurrent bacterial and fungal infections. However, it is interesting that the spectrum of infections is fairly limited, with the most common pathogens being *Staphylococcus aureus, Burkholderia cepacia, Serratia marcescens, Nocardia* spp., and *Aspergillus* spp.[1-3] Other infecting organisms occur less frequently but are rare outside of CGD, and these include *Chromobacterium violaceum, Aspergillus nidulans,* and *Granulibacter bethesdensis.*[3]

Infections in CGD are typically of the lung, lymph nodes, liver, and bone (Fig. 37.1).

Identification of the infecting organism is essential in CGD to guide antimicrobial therapy. CGD is not only characterized by exuberant granulomatous inflammation, both in areas without clear infection, such as in the gastrointestinal (GI) and genitourinary tract, but also in response to infection.[1,2] Therefore although necrotic and purulent centers may form in liver and lymph node infections, the yield with drainage may be poor because of the thicker consistency of granulomatous inflammation. At times, the infected lymph nodes may need resection to cure infections. Likewise, in lung infections, fine-needle aspiration frequently provides a higher yield than bronchoscopy because of the nature of inflammation. In addition, it is important to alert the microbiology laboratory when *G. bethesdensis* is suspected, such as with lymphadenitis, as growth requires special media.

The granulomatous inflammation seen in CGD infections may be intense enough to impede successful treatment of infection solely with antimicrobials and necessitate corticosteroid addition to appropriate antimicrobials. For instance, "mulch pneumonitis" occurs with large inhalations of decaying organic matter, such as mulch.[4] A diffuse pneumonitis associated with *Aspergillus* results and can be quite fulminant, with a high mortality if the inflammatory response is not treated (*e.g.,* with corticosteroids) in addition to antifungals. There is suggestion that the addition of corticosteroids may help with other infections in CGD, such as *Nocardia* pneumonia and *S. aureus* liver abscesses.[5,6]

Trimethoprim–sulfamethoxazole (TMP-SMX) is effective against the majority of bacterial pathogens in CGD and thus is an ideal prophylactic antibiotic and has been shown to significantly decrease bacterial infections.[7] Itraconazole was shown to be effective in preventing some of the fungal infections.[7] The newer triazoles, including voriconazole and posaconazole, have not been studied as prophylactic antimicrobials in this setting but have an extended spectrum and would likely be effective as well. Toxicities of extended use with certain antimicrobials need to be considered; for instance, voriconazole is associated with photosensitivity and increased skin cancers with prolonged use, as well as fluoride toxicity in rare cases.[8,9]

Leukocyte Adhesion Deficiencies

Leukocyte adhesion deficiencies (LADs) result from the inability of neutrophils to migrate to the site of infection.[2] LAD-1 is most frequent, resulting from a defect in β_2 integrin and presenting typically with failure of umbilical cord separation and omphalitis. The spectrum of infection is not as specific as with CGD but is limited typically to bacterial infections. Gingivitis and periodontitis lead to frequent oral bacterial infections, and necrotizing ulcerative skin infections are common, typically with *S. aureus* or gram-negative bacteria (GNB). Although primarily a defect of neutrophils resulting in bacterial infections, viral

TABLE 37.1 Infection Susceptibility of Select Primary Immunodeficiencies

Immunodeficiency	Genetic Defect	Functional Defect	Infection Susceptibility
Chronic granulomatous disease	Gp91^{phox}, p22^{phox}, p40^{phox}, p47^{phox}, p67^{phox}	Defect in nicotinamide adenine dinucleotide phosphate (NADPH) oxidase leading to abnormal superoxide production	Catalase positive bacteria (*e.g., Staphylococcus aureus, Burkholderia, serratia, Nocardia*) and filamentous molds
Leukocyte adhesion disorder-1 (LAD-1)	β_2 integrin	Neutrophil migration	Bacteria, typically *S. aureus,* gram-negative
Severe congenital neutropenia	*HAX1, ELANE*	Neutropenia	Bacteria, typically streptococci, *S. aureus,* gram-negative
X-linked agammaglobulinemia	Bruton tyrosine kinase (BTK)	Absence of B cells, antibody production	Encapsulated bacteria, enterovirus, *Helicobacter,* and related species
CD40 ligand deficiency	CD40 ligand	Impaired B-cell class switching	Encapsulated bacteria, *Pneumocystis jiroveci, Cryptosporidium*
Severe combined immunodeficiency (SCID)	Multiple genes, such as *IL2RG, RAG1/2, ADA, JAK3,* etc.	T-cell lymphopenia, variable B- and natural killer (NK)-cell expression	Bacteria, virus, *P. jiroveci, Candida,* Bacille Calmette-Guérin (BCG)
DiGeorge syndrome	Deletion of chromosome 22q11 in majority	Thymic hypoplasia or aplasia	Viruses, opportunists infrequent
Autosomal dominant hyper-IgE syndrome (Job's syndrome; AD-HIES)	Signal transducer and activator of transcription 3 (STAT3)	Impaired T-helper-17 (Th17) cell differentiation	*S. aureus, Candida,* dimorphic fungi; secondary infection of pneumatoceles with molds, gram-negative bacteria and nontuberculous mycobacteria
Dedicator of cytokinesis 8 (DOCK8) deficiency	DOCK8	T-cell lymphopenia, defect still being delineated	*S. aureus, Candida, Molluscum contagiosum,* human papillomavirus (HPV), herpes viruses
Interleukin-12 (IL-12)/interferon (IFN)-γ axis defects	IFN-γR1, IFN-γR2, IL-12, IL-12R, NEMO, STAT1	Failure of signal transducer and activator of transcription 1 (STAT1) activation, intracellular killing	*Mycobacteria, Salmonella,* dimorphic fungi
Complement C5–9 defects	Specific complements	Impaired membrane attack complex killing	*Neisseria* species

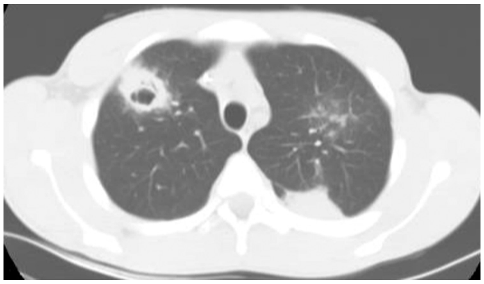

FIG 37.1 Chest computed tomography (CT) scan of a *Nocardia* pneumonia in a 17-year-old man with chronic granulomatous disease.

KEY CONCEPTS

Infection Risks in Primary Immunodeficiencies

- Neutrophil defects present primarily with bacterial and fungal infections.
- Humoral immunodeficiencies present with impaired antibody formation and primarily sinopulmonary infections with encapsulated organisms.
- Severe primarily T-cell defects usually present with opportunists, such as *Pneumocystis.*
- Abnormalities of the interleukin-12 (IL-12)/interferon (IFN)-γ axis commonly present with nontuberculous mycobacteria (NTM) infections.
- Cytokine autoantibody syndromes are being increasingly recognized with infection susceptibility dependent on the involved cytokine.

warts are not infrequent. Fungal infections are unusual. Little is known about antimicrobial prophylaxis for LAD-1, but typically prophylaxis with some coverage for oral flora, *S. aureus,* and GNB is provided, such as with amoxicillin/clavulanate.[7] Other rare neutrophil defects, including Chediak-Higashi and Griscelli syndromes, also are characterized by recurrent pyogenic infections.

Quantitative Phagocyte Defects

Neutropenia is the most common quantitative defect of phagocytes and typically results from cytotoxic agents, as discussed later in this chapter. Autosomal recessive defects in *HAX1* cause Kostmann syndrome, a type of severe congenital neutropenia, which typically presents in infancy with recurrent bacterial infections.[10] Autosomal dominant defects in the neutrophil elastase gene *ELANE* cause severe congenital neutropenia and cyclic neutropenia. Benign ethnic neutropenia is seen primarily in individuals of African descent and is usually asymptomatic. Secondary causes of neutropenia also include antineutrophil antibodies and hypersplenism with sequestration.

Infections associated with neutropenia relate to the etiology as well as the degree and duration of neutropenia. Cyclic neutropenia may be largely asymptomatic, with self-limited fevers and oral ulcers or cervical lymphadenopathy, as opposed to the severe chronic neutropenia of infancy that has more serious infections. Neutropenia is most frequently associated with bacterial infections, often localized to the mouth, cervical lymph nodes, lungs, and perianal area, with both gram-positive bacteria (GPB) and GNB. Fungal infections are more frequent in the prolonged and severe neutropenias associated with hematological malignancies and hematopoietic transplantation. Fever in the setting of neutropenia requires rapid assessment, with particular focus on physical examination of areas with high bacterial colonization, such as the oral cavity and perianal region, as well as sites of indwelling intravenous catheters. Empiric broad-spectrum antibiotics after obtaining appropriate cultures are often prudent.

Monocytopenia has been described in GATA2 deficiency and associated with disseminated Bacille Calmette-Guérin (BCG) with interferon (IFN) regulatory factor 8 (*IRF8*) deficiency.[11,12] The described spectrum of GATA2 deficiency is increasing and includes MonoMAC syndrome, Emberger syndrome with lymphedema and myelodysplasia, familial leukemia, aplastic anemia, and childhood-onset neutropenia.[11] The predominant clinical findings are disseminated mycobacteria; fungal infections, such as disseminated histoplasmosis; warts with cervical and vulvar dysplasia; pulmonary alveolar proteinosis (PAP); myelodysplasia; and leukemia. Onset is typically in later childhood and adulthood, and in addition to monocytopenia, lymphocytopenia may be present. When the patient is symptomatic, treatment is typically with HSCT.

HUMORAL IMMUNODEFICIENCIES (Chapter 34)

Humoral immunodeficiencies are characterized by absent or defective B cells with resultant lack of specific antibody responses, leading predominantly to infections with encapsulated bacteria. There is a spectrum of severity with X-linked agammaglobulinemia (XLA) characterized by a total absence of B cells and presentation in the first years of life and the later presentations of common variable immunodeficiency (CVID).[13]

Humoral immunodeficiencies are characterized by recurrent ear, sinus, and lung infections, with typical bacterial etiologies being *Streptococcus pneumoniae* and *Haemophilus influenzae*. Despite immunoglobulin (Ig) replacement, bronchiectasis may occur, and with it, the spectrum of pulmonary infections may broaden requiring careful microbiological monitoring. Neutropenia may occur with XLA and CD40 ligand deficiency, frequently when replacement Ig is not provided, and may be associated with a broader spectrum of infection, with more severe *S. aureus* and *Pseudomonas* infections. Chronic *Mycoplasma* and *Ureaplasma* spp. infections can occur leading to lung disease and arthritis. *Giardia* can be a source of GI disease. In severe humoral defects, such as XLA, persistent *Helicobacter, Flexispira,* and *Campylobacter* spp. infections are infrequent and are characterized by ulcerative skin lesions.[14,15] These infections require a high index of suspicion to be identified, as special microbiology media with longer lengths of incubation may be required. Eradication of infection, even with a combination of intravenous antibiotics, is often difficult. Severe meningoencephalitis with enteroviral infections may occur and can be quite devastating and difficult to treat. Replacement Ig therapy, given intravenously or subcutaneously, is used to minimize the recurrent encapsulated bacterial infections and diminish the risk of enterovirus infection. The role of prophylactic antibiotics is not well studied and varies among centers.

CD40 ligand deficiency (X-linked hyper-IgM) is the most common of the Ig class switch defects.[13] Sinopulmonary infections similar to XLA typically arise in early childhood. However, as opposed to XLA, *Pneumocystis jiroveci* pneumonia (PJP) occurs and may be the initial infection. Other infections indicative of T-cell defects occur as well, including cytomegalovirus (CMV) infection, toxoplasmosis, and cryptosporidiosis. Cryptosporidial infection can be a chronic and severe problem and may lead to sclerosing cholangitis.

PRIMARY CELLULAR AND COMBINED IMMUNODEFICIENCIES (Chapter 35)

Severe Combined Immunodeficiency

Severe combined immunodeficiency (SCID) results from a severe deficiency in the number or function of T cells. Depending on the genetic defect, B and/or natural killer (NK) cells are affected as well. Presentation is typically very early in life, with significant compromise within the first few months of life. In recent years, there has been more recognition of “leaky” forms of SCID, in which the defects are not complete and presentation can be later and more variable.[16]

SCID is associated with recurrent and persistent viral, bacterial, and fungal infections. PJP frequently occurs in early infancy, and prophylaxis should be provided. Chronic mucocutaneous candidiasis (CMC) is frequent and may require antifungal suppressive therapy. Diarrhea from viral and other etiologies frequently leads to failure to thrive. Severe respiratory viral infections and CMV also occur. In countries where BCG vaccine is given, disseminated infection may result; transplantation may lead to an immune reconstitution syndrome in which sites of BCG infection become inflamed and abscesses may form.

DiGeorge Syndrome

Immune deficiency in DiGeorge syndrome results from varying degrees of thymic hypoplasia or aplasia.[17] Other manifestations include congenital heart disease, characteristic facies and palate anomalies, hypocalcemia, and learning disabilities. With the exception of severe cases in which there is thymic aplasia and severe T-cell lymphopenia, opportunistic infections (OIs) are infrequent. Upper respiratory tract infections predominate, and prophylactic antibiotics may not be necessary. With the more mild defects, live viral vaccination may be considered safe.[18]

Autosomal Dominant Hyper-IgE Syndrome (Job’s Syndrome)

Autosomal dominant hyper-IgE syndrome (Job’s syndrome; AD-HIES), resulting from *STAT3* mutations, has been frequently characterized as a phagocytic defect. However, in recent years, it has been recognized that the immune defects center around the failure of T-helper 17 (Th17) cell differentiation and a decrease in memory T and B cells.[19,20] A lack of Th17 cells resulting in impaired interleukin-17 (IL-17) and IL-22 signaling and diminished antimicrobial peptide upregulation appears to at least explain some of the infection susceptibility.

AD-HIES is characterized by recurrent skin and lung bacterial infections, CMC, eczema, and a variety of connective tissue, skeletal, and vascular abnormalities.[20] *S. aureus* skin abscesses start early in life, and *S. aureus* colonization appears to drive the eczema. *S. aureus, S. pneumoniae,* and *H. influenzae* pneumonias typically start in the first few years of life, and prophylactic antimicrobials, such as TMP-SMX, can be useful in reducing the frequency. Healing of pneumonias appears aberrant, and bronchiectasis and pneumatoceles frequently result. The lung with these parenchymal abnormalities is then predisposed to mold infections (most frequently *Aspergillus* and *Scedosporium* spp.) and gram-negative infections, such as with *Pseudomonas aeruginosa* and nontuberculous mycobacteria (Fig. 37.2). These secondary infections can be quite difficult to eradicate. CMC is the most frequent fungal infection. PJP is much less frequent, typically occurring in infancy, potentially as the first pneumonia.

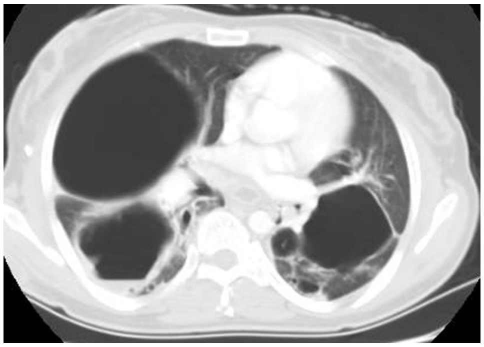

FIG 37.2 Chest computed tomography (CT) scan of a pneumatocele with secondary *Mycobacterium abscessus* and *Pseudomonas aeruginosa* infection in a 25-year-old woman with autosomal dominant hyper-IgE syndrome (Job's syndrome; AD-HIES).

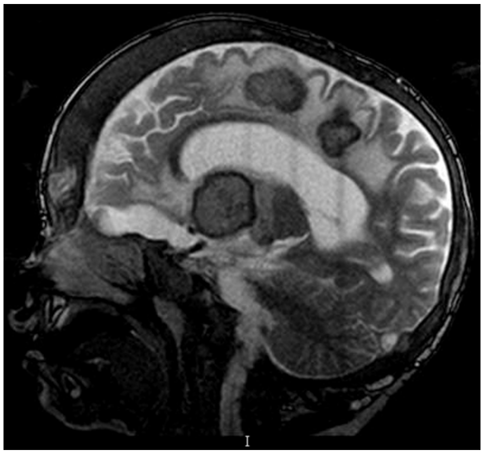

FIG 37.3 Brain magnetic resonance imaging (MRI) scan showing Bacille Calmette-Guérin (BCG) abscesses in a 3-year-old boy with an interferon (IFN)-γ receptor defect.

Disseminated cryptococcal infection has been described causing meningitis or GI infection. *Histoplasma* typically has caused disease of the GI tract, and *Coccidioides* infection has caused meningitis.[21]

DOCK8 Deficiency

Dedicator of cytokinesis 8 (DOCK8) deficiency is a combined defect that is one cause of an autosomal recessive hyper-IgE syndrome (AR-HIES).[22] Compared with AD-HIES, DOCK8 deficiency is characterized by severe cutaneous viral infections in addition to sinopulmonary infections. Recurrent cutaneous infections with herpes simplex virus (HSV) and varicella-zoster virus (VZV) occur, as well as severe, disfiguring warts and *Molluscum contagiosum* infection. DOCK8 deficiency has an overall worse prognosis than AD-HIES, with frequent occurrence of malignancies, typically squamous cell carcinoma and lymphomas.

Defects of the IL-12/IFN-γ Axis

Defects of the IL-12/IFN-γ axis are characterized primarily by mycobacterial infections. Monocyte-derived macrophages ingest intracellular bacteria, such as *Mycobacterium* and *Salmonella,* leading to IL-12 secretion. IL-12 binds to its receptor on T lymphocytes and NK cells leading to IFN-γ secretion, which then binds to its heterodimeric receptor on macrophages, activating microbial killing through signal transducer and activator of transcription 1 (STAT1). Many defects along this pathway have been described, including mutations in IL-12, IL-12 receptor, IFN-γ receptor1 and 2, STAT1, and nuclear factor (NF)-κB essential modulator operon (NEMO).[23,24] Defects along this pathway show varying susceptibility to nontuberculous mycobacteria (NTM), *Salmonella,* and endemic dimorphic fungal infection (Fig. 37.3). For example, individuals with dominant IFN-γ receptor defects retain some IFN-γ signaling and tend to have localized NTM infections, often presenting with osteomyelitis, and infrequently other OIs, such as disseminated histoplasmosis. Treatment of the dominant IFN-γ receptor defects is typically successful with combination antimycobacterial agents with or without exogenous IFN-γ. In contrast, autosomal recessive IFN-γ receptor defects, in which there is typically no residual IFN-γ signaling, have much more severe disease, with earlier onset of disseminated NTM or BCG disease, poor response to therapy with frequent relapse, and a greater susceptibility to infection, including some viral susceptibility. Death in childhood is frequent, and HSCT is typically considered.

Compared with loss of function STAT1 mutations, which are characterized by disseminated NTM infections, gain-of-function STAT1 (GOF-STAT1) mutations have a much broader infection susceptibility pattern and varied presentations.[25] Although initially described as causing CMC, GOF-STAT1 mutations are also associated with disseminated endemic mycoses, such as *Coccidioides* infection, viral infections including those of the herpes family and progressive multifocal leukoencephalopathy (PML), and bacterial infections. GOF-STAT1 mutations can also be associated with NTM infections.

COMPLEMENT DEFICIENCIES (Chapter 21)

Infections with encapsulated organisms are the typical manifestations of complement defects.[26] C3 deficiency is associated with recurrent and severe infections with *S. pneumoniae, H. influenzae,* and *Neisseria meningitidis,* whereas deficiencies of the components of the terminal pathway composing the membrane attack complex, C5-9, result in *N. gonorrhoeae* and *N. meningitidis* infections.

ASPLENIA

The spleen acts as both a source for antibody production and a filter to remove pathogens through phagocytic cells. Spleens can be physically absent, either congenitally or through surgical resection (*e.g.,* with intractable hemolytic anemia or thrombocytopenia, malignancy, trauma), or functionally absent as is seen with increased age in sickle cell disease. Infections associated with asplenia include sepsis with encapsulated bacteria, namely, *S. pneumoniae* and *H. influenzae,* and with *Babesia,* a protozoan that infects erythrocytes and causes fever and hemolysis with asplenia.[26] Similar to babesiosis, malaria infection can be more severe in patients without a spleen. The risk of infection differs with the etiology of asplenia, with splenectomy associated with trauma having the lowest risk as typically small amounts of splenic tissue remain. In addition, infection with encapsulated organisms appears to be more common in children with asplenia than in adults with asplenia.

SECONDARY NON–MEDICATION-ASSOCIATED IMMUNODEFICIENCY

Cytokine Autoantibodies

In recent years, there has been greater recognition of susceptibility to infection associated with anticytokine autoantibodies.[27-30] Autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APOCED) is a disorder caused by mutations in the autoimmune regulator gene (*AIRE*). Many autoimmune manifestations are seen in APOCED, including hypoparathyroidism, diabetes, and adrenal failure as a result of persistent autoreactive T cells caused by failure of thymic deletion. The main infectious complication is severe CMC. Neutralizing autoantibodies to IL-17 and IL-22 have been detected and may contribute to the occurrence of CMC, similar to other defects along the Th17/IL-17/IL-22 pathway, such as AD-HIES.[29,30] Neutralizing autoantibodies to IFN-γ leading most frequently to disseminated NTM infections have been described.[27] This disorder typically presents in adulthood and has an increased prevalence in Asians. Although the primary manifestation of autoantibodies against granulocyte macrophage–colony-stimulating factor (GM-CSF) antibodies is PAP, an increased frequency of OIs, such as with *Nocardia* and *Cryptococcus,* has been described.[30]

THERAPEUTIC PRINCIPLES

Prevention of Infection in Patients With a Defect in Host Defenses

- Use of prophylactic antibiotics in patients at high risk for a specific type of infection
- Immunization to prevent specific bacterial and viral infections:
    - Active immunization, especially in patients who should be capable of mounting an effective response (*e.g.,* before elective splenectomy or before elective initiation of immunosuppressive therapy)
    - Passive immunization through administration of high-titer pooled immunoglobulin to patients exposed to or at high risk of specific viral infections.

INFECTIONS IN PATIENTS RECEIVING IMMUNOSUPPRESSIVE MEDICATIONS

Immunosuppressive drugs have been used for over 60 years[31] and are essential for the management of autoimmune/inflammatory diseases and hematological and oncological malignancies and in transplant recipients. Early immunosuppressive agents lacked specificity and therefore led to serious and numerous adverse effects. Newer immunosuppressive agents have revolutionized the treatment of multiple diseases, but many of these have led to an increase in specific infectious complications. Knowledge of the particular infection or treatment associations is imperative.[32]

Described below are the most common classes of drugs that have been linked to infectious complications. Notably, immunosuppressive agents are frequently used in combination, and therefore establishing clear causality is challenging.

Cytotoxic Agents (*e.g.,* Cyclophosphamide, Methotrexate, Azathioprine)

Initially developed to control neoplastic growth in oncological and hematological malignancies, cytotoxic drugs have also found their niche as an essential component of the conditioning regimen for HSCT and solid organ transplantation (SOT), as immunomodulators in autoimmune and inflammatory disorders, and graft-versus-host disease (GvHD). These drugs inhibit B-cell and T-cell proliferation and hinder cellular and humoral immune responses in a dose-dependent fashion.[33] One of the main side effects of these agents is hematopoietic toxicity; they induce neutropenia to varying degrees. Fever occurs during chemotherapeutic-induced neutropenia in 10–50% of patients with solid tumors and in >80% of those with hematologic malignancies.[34] Common sites of infection include the intestinal tract, lungs, and skin; bacteremia occurs in up to 25% of patients. Probably because of the high incidence of indwelling catheters and widespread use of prophylactic antibiotics, currently coagulase-negative staphylococci are the most common blood isolates, followed by drug-resistant Enterobacteriaceae and nonfermenting GNB (*e.g., P. aeruginosa*).[34] Invasive mold infections (*e.g.,* aspergillosis) typically occur after prolonged neutropenia (>2 weeks). Invasive yeast (usually *Candida* spp.) infections are more commonly seen in patients with severe mucositis and neutropenia. Detailed guidelines for the use of antimicrobial agents in the setting of chemotherapy-induced neutropenic fever have been published.[34] Although bacterial infections are the most common infections, when used as immunomodulators, a higher frequency of OIs, such as PJP, and infections with *Listeria* spp., NTM, *Cryptococcus,* and VZV, has been described.

Glucocorticoids

Depending on the dose and duration, glucocorticoids can induce a vast range of immune defects through decreasing cytokine production (IL-1, IL-6, and tumor necrosis factor-α [TNF-α]), and impairing neutrophil and lymphocyte trafficking and function. Infections are a frequent complication of corticosteroid use.[32] Bacterial infections are the most common infectious complication, but opportunistic fungal, viral, and mycobacterial infections are also seen, particularly with high doses and long duration of systemic therapy. Some associated infections include GPB and GNB, superficial and invasive candidiasis, invasive aspergillosis and nocardiosis, cryptococcosis, PJP, listeriosis, endemic mycoses, tuberculosis (TB), and infections with NTM, and VZV, among others. Outside of the setting of SOT and HSCT, routine use of antimicrobials for patients receiving corticosteroids is not recommended, except for anti-TB treatment (*e.g.,* isoniazid) for those with a positive tuberculin skin test (purified protein derivative [PPD]) or a positive IFN-γ release assay, and TMP-SMX in those receiving high-dose steroid for extended periods.[35] Alternate-day use of corticosteroids has been associated with a lower risk of severe infection; therefore whenever possible, this dosing schedule should be used.[31]

Calcineurin Inhibitors and Mammalian Target of Rapamycin Inhibitors

The calcineurin inhibitors, cyclosporine and tacrolimus, have been cornerstones in improving the outcome of transplant recipients by reducing T-cell function and thus preventing allograft rejection in SOT and GvHD in HSCT. Infectious complications, typically viral, seem to be dose dependent and seen more often when these drugs are used in combination with other immunosuppressants.[32,33] The mammalian target of rapamycin (mTOR) inhibitors sirolimus and everolimus have been associated with a lower incidence of CMV infection, compared with other immunosuppressive agents used in transplantation.[32] Although impaired wound healing has been seen, this has not correlated with an increased incidence of infections.

Mycophenolate Mofetil

Mycophenolate mofetil (MMF) is a prodrug of mycophenolic acid, which inhibits inosine monophosphate dehydrogenase, a key enzyme in purine synthesis. It is a cytotoxic drug with antiproliferative effect on T and B lymphocytes.[33] In addition to its potential myelosuppressive effect, it has been associated in SOT to a higher risk of CMV infection.[32]

Antithymocyte Globulin

Antithymocyte globulin (ATG) is a polyclonal Ig prepared by immunizing horses or rabbits with human thymocytes and harvesting the IgG. These antibodies produce a profound lymphopenia that can last well beyond 1 year. Used for induction or rejection therapy in transplantations, their use has been associated consistently with a greater risk of CMV and posttransplantation lymphoproliferative disease (PTLD).[36] CMV prophylaxis or preemptive therapy is recommended in transplant recipients that receive ATG. Because these are foreign proteins, serum sickness can also develop between 1 and 2 weeks after treatment.

Monoclonal Antibodies and Small Molecules

Monoclonal antibodies (mAbs) and small molecules target specific cellular steps, making it possible to manipulate disease pathways for previously untreatable illnesses. Many of these biological agents interfere with specific aspects of the immune system. Highlighted below are those that have a key infection susceptibility pattern. Others with more subtle increases in infections are also included in Table 37.2.

Tumor Necrosis Factor-α Inhibitors

TNF-α is a cytokine that plays a central role in macrophage and phagosome activation, differentiation of monocytes into macrophages, recruitment of neutrophils and macrophages, and granuloma formation and maintenance. Blockade results in an increased risk of infection, particularly in the first few months after treatment.[37,38] Infections characterized by granulomas have been described most frequently, in particular TB and NTM infections, but also disseminated histoplasmosis and coccidioidomycosis.[39] Other notable infections are listeriosis, legionellosis, salmonellosis, recurrent or relapsing leishmaniasis, overwhelming *Plasmodium falciparum* infection, and invasive mold infections (*i.e.,* aspergillosis and mucormycosis). Risk of certain viral infections also appears to be increased, particularly VZV infection. Several cases of severe hepatitis B virus (HBV) reactivation in patients with positive surface antigen at the start of treatment have been reported, many of whom developed hepatic failure. Patients receiving anti–TNF-α therapy should be screened for TB (latent or active), HBV, and HCV before starting treatment, and treated accordingly.[38] Patients with latent TB should receive isoniazid for 6–9 months. Ideally, patients would have received at least 3 weeks of isoniazid before therapy with biologicals; however, in truly urgent cases, this can be done simultaneously. In patients that are hepatitis B surface antigen (HbsAg) positive, baseline HBV DNA levels should be obtained and antiviral prophylaxis or treatment offered. All HBV-seronegative patients should be vaccinated against hepatitis B and seroconversion documented.

TABLE 37.2 Selected Monoclonal Antibodies and Small Molecules and Their Risk of Infection

Drug Name	Target	Serious Infections
Adalimumab Certolizumab pegol Etanercept Golimumab Infliximab	TNF-α*	TB, NTM infection, endemic mycoses, listeriosis, candidiasis, invasive mold infections, nocardiosis, bacterial infections, reactivation of VZV and HBV infections, severe malaria, and leishmaniasis
Rituximab	CD20	HBV infection reactivation, PML, PCP, enteroviral meningoencephalitis, CMV disease, VZV infection, babesiosis, parvovirus infection, nocardiosis
Anakinra Rilonacept	IL-1	Bacterial infections (cellulitis and pneumonia)
Alemtuzumab	CD52	Herpes viruses reactivation (EBV, VZV, CMV, HHV-6), severe respiratory viral infections (with adenovirus, RSV, parainfluenza virus, influenza virus), PCP, invasive mold infections, histoplasmosis, cryptococcosis, PTLD, bacterial meningitis, toxoplasmosis, PML, parvovirus infection, nocardiosis, TB, NTM infection, acanthamebiasis, and *Balamuthia mandrillaris* infection
Muromonab	CD3	Bacterial infections; listeriosis; nocardiosis; aspergillosis; candidiasis; cryptococcosis; toxoplasmosis; infections with CMV, HSV, VZV, adenovirus, RSV, and enteroviruses; and PCP
Basiliximab Daclizumab	CD25	Bacterial infections; infections with CMV and HSV; EBV-associated PTLD; infections with RSV, adenovirus, influenza, and BK virus; invasive mold infections; candidiasis; nocardiosis; TB; NTM infection; toxoplasmosis
Natalizumab	α-4 Integrin	PML, respiratory viral and bacterial infections, UTI, viral meningitis and encephalitis, CMV infection, IA, PCP, VZV infection, NTM infection, cryptosporidiosis
Abatacept Belatacept	T-cell costimulation blockade	Bacterial infections, EBV-associated PTLD
Alefacept	Inhibits T-cell activation	1 case of *Mycobacterium avium intracellulare* (MAI) bursitis, 1 case of nocardiosis when coadministered with infliximab
Brodalumab	IL 17 receptor A	Mucocutaneous candidiasis
Bortezomib	Proteasome inhibitor	Herpes zoster
Gemtuzumab	CD33	Bacteremia, bacterial pneumonia, and HSV reactivation.

*TNF-α, tumor necrosis factor-α; IL-1, interleukin-1; TB, tuberculosis; NTM, nontuberculous mycobacteria; VZV, varicella-zoster virus; HBV, hepatitis B virus; PML, progressive multifocal leukoencephalopathy; PCP, *Pneumocystis jiroveci* pneumonia; CMV, cytomegalovirus; EBV, Epstein-Barr virus; HHV-6, human herpes virus 6; RSV, respiratory syncytial virus; PTLD, posttransplantation lymphoproliferative disease; HSV, herpes simplex virus; UTI, urinary tract infection; IA, invasive aspergillosis.

Rituximab

Rituximab is a chimeric murine–human mAb that targets CD20 on mature B lymphocytes. It results in rapid and profound depletion of B cells that can last up to several months.[40] In most adults, serum Ig levels remain largely stable, since plasma cells do not express CD20. Initial trials suggested that rituximab had minimal effect on the occurrence of infections; however, more recent meta-analyses have reported a higher risk of infections, especially with repeated administration and in patients with underlying immune defects or concomitant significant immunosuppression.[40] HBV reactivation occurs, and there have been reports of fulminant hepatitis and death after rituximab treatment, particularly when used in combination therapy (*e.g.,* rituximab with cyclophosphamide, doxorubicin, vincristine, and prednisone [R-CHOP]). Also a reverse seroconversion phenomenon has been described, with loss of protective HBV surface antibodies and reactivation.[38] Assessment of HBV status before starting rituximab is recommended. To reduce the risk of reactivation, HBV suppression with antiviral medication should be considered.

Since the initial approval of rituximab, there have been over 280 cases of PML associated with its use. Most cases have been reported in patients with hematological malignancies; however, some have been reported in patients with autoimmune or inflammatory diseases, who take other immunosuppressants as well. Rituximab now carries a black box warning about the risk of PML and death.[41] There have been many reports of PJP following use of rituximab, although most patients also received other immunosuppressive therapies. The need for PJP prophylaxis with its use remains to be determined. The greatest risk of infection appears to be related to viral reactivation, particularly in children; as usual, this is confounded by prior or concomitant immunosuppressive medications. In children with immune-mediated neurological diseases, infections after rituximab use are common; even lethal CMV disease has been reported.[42] Other rare infections that have been described are enteroviral meningoencephalitis, CMV disease, disseminated VZV infection, refractory babesiosis, parvovirus B19 infection, and nocardiosis.[37]

Alemtuzumab

Alemtuzumab is a humanized IgG1 that targets CD52 on B and T lymphocytes, monocytes, macrophages, and NK cells. It lyses these cell populations and results in profound and sustained deficits in cellular and humoral immunity that lasts for several months; CD4 and CD8 cell count reach their nadir approximately 4 weeks after treatment, but median counts remain at <25% of baseline for approximately 9 months.[38] Opportunistic and nonopportunistic infections have been associated with its use, particularly reactivation of herpes virus (*e.g.,* Epstein-Barr virus [EBV], CMV, disseminated VZV) and fungal infections (*e.g.,* PJP, invasive molds, and dimorphic fungi). Moreover, several cases of TB and NTM infection have been reported. The incidence of these OIs varies with the administered dose and whether it is used as a single agent or in combination with other immunosuppressants (*e.g.,* induction therapy [4.5%] versus treatment for rejection [21%] in SOT).[37,38] When used for T-cell depletion in allogeneic HSCT (allo-HSCT) it has been associated with a very high risk of CMV reactivation (50–85%) and disease, severe adenovirus infection, human herpesvirus-6 (HHV-6) encephalitis, respiratory viral infections that frequently progress to pneumonia, and PTLD. Other infections that have occurred are overwhelming bacteremia, bacterial meningitis, toxoplasmosis, PML, disseminated amoebiasis, parvovirus infection, and nocardiosis. All patients receiving alemtuzumab should receive PJP and herpesvirus prophylaxis for a minimum of 2 months after therapy or until CD4 counts are ≥200 cells/μL (Campath package insert). Given the high incidence of CMV reactivation and disease, prophylaxis or preemptive therapy is warranted.

Daclizumab and Basiliximab

Daclizumab and basiliximab are humanized and chimeric mAbs, respectively, that target CD25, the α chain of the IL-2 receptor complex expressed on activated alloantigen-reactive T lymphocytes. They competitively inhibit IL-2 binding and prevent IL-2 mediated activation of lymphocytes and cytokine release. They are mainly used in transplantation to prevent rejection or steroid-refractory GvHD.[37] When used as prophylaxis for rejection in SOT, their use does not seem to be associated with an increased risk in infections. In allo-HSCT, high rates of mortality and of OIs (95%) have been reported in patients receiving daclizumab for steroid-refractory GvHD; however, given the high risk of OIs in this population in general, the actual role of daclizumab is unclear. Infections described in this setting are common bacterial, viral (CMV, BK virus, adenovirus, HSV, RSV, influenza virus), EBV-associated PTLD, invasive fungal infections (mold and yeasts), as well as *Legionella* and *Nocardia* and NTM infections, TB, and toxoplasmosis.[38]

Natalizumab

Natalizumab is a humanized IgG4 that targets the α_4 subunit of $\alpha_4\beta_1$ and $\alpha_4\beta_7$ integrins, found in lymphocytes; it inhibits their binding to cellular adhesion molecules (vascular cell adhesion molecule-1[VCAM-1] and mucosal addressin-cell adhesion molecule-1 [MAdCAM-1]) in the central nervous system (CNS) and the GI tract, thereby attenuating inflammation in these tissues.[38,43] It is associated with a profound decrease in CD4, CD8, and CD19 lymphocytes in cerebrospinal fluid (CSF), and it is used in the treatment of multiple sclerosis and Crohn's disease. Natalizumab was temporarily withdrawn from the market in 2005 after three cases of PML were reported in patients with prolonged exposure. It has now been reintroduced with a black box warning about the risk of PML. Based on retrospective global surveillance data, the overall incidence of PML in natalizumab treated patients is 1.01 cases/1000 patient-years. However, the risk of PML is significantly increased in patients who have detectable anti-JC virus antibodies before the initiation of therapy, had prolonged exposure to natalizumab (>24 months), and had prior use of immunosuppressants (11.1 cases/1000 patients [95% confidence interval (CI) 8.3–14.5]). The incidence in patients with no detectable anti-JC virus antibodies is calculated at 0.09 cases/1000 patients (95% CI 0–0.48).[43] Increases in bacterial and viral infections and OIs have been reported as well, but most patients with these infections were receiving concurrent immunosuppression.

Bortezomib

Bortezomib is a dipeptide boronate proteasome inhibitor that causes G2–M cell cycle arrest and apoptosis, which ultimately impacts T-cell immunity. It is now approved for the treatment of multiple myeloma and mantle cell non-Hodgkin lymphoma. An increased incidence of herpes virus infections, in particular VZV infection, has been reported. The incidence in patients with myeloma treated with bortezomib is around 13–22% and in relapsed/refractory mantle cell lymphoma around 10.3%, with age ≥65 years as the only predictive factor.[44]

INFECTIONS IN SOLID ORGAN TRANSPLANTATION

KEY CONCEPTS

Determinants of the Risk for Infections in Transplant Recipients

- Epidemiological exposures (*e.g.,* residing in a *Histoplasma* endemic area)
- Immunosuppressive drugs
- Antimicrobial prophylaxis
- Type of transplantation (*e.g.,* cord transplant vs matched related donor transplantation)
- Time after transplantation

Despite significant improvement in the survival of SOT recipients, infectious complications remain a major cause of morbidity and mortality. The risk of infection is determined by the interaction of various factors, such as age of the recipient, type of transplantation, invasive procedures, dose and duration of immunosuppressive drugs, epidemiological exposures of both donor and recipient, use of antimicrobial prophylaxis, donor–recipient serological status to certain infections (*e.g.,* CMV infection, EBV infection, toxoplasmosis), and ongoing viral replication (so-called indirect effects).[45] Assessment of a recipient's risk for infection should help tailor specific prophylactic strategies and infectious workup when an infection is suspected.

Age is an important determinant of susceptibility to infections; it impacts the likelihood of prior exposures to microbial pathogens, either by primary infection or vaccination. History of exposure can have either positive or negative effects. Older patients are more likely to have encountered pathogens that can remain latent and reactivate at the time of transplantation (*e.g.,* CMV); younger patients have a higher risk of acquiring primary infections after transplantation, and these infections tend to be more severe than disease secondary to reactivation of a latent infection. In addition, preexisting immunity can have a protective effect against clinical disease (*e.g.,* EBV-associated PTLDs).[45]

The type of allograft affects the specific infectious risk, usually as a result of technical factors associated with the transplantation procedure, but is also inherent to the transplanted organ. For example, urinary tract infections are most common after kidney transplantation, as a result of either catheter placement or ureteric stenting. BK virus is ubiquitous, but BK virus–associated transplant nephropathy is most common after kidney transplantation, and it is an important cause of allograft loss. Infection after liver transplantation frequently results from leaks from biliary and GI anastomoses. Cardiac assist devices in heart transplant recipients are a frequent source of infection. Tracheal anastomotic infections, particularly caused by fungi, are a significant complication of lung transplantation. In single lung transplantations, recurrent infections of the native lung, such as with GNB or fungi, can extend to the transplanted lung. In small intestine transplantation, opportunistic and nonopportunistic viral infections of the GI tract (*e.g.,* with norovirus) are common; these can be severe and even life threatening.[45]

Despite all the differences in individual risk of infection, the general patterns of infection in the absence of antimicrobial intervention are similar among those undergoing SOT. This predictable temporal pattern has enabled the institution of specific prophylactic strategies and in the development of an infection differential diagnosis.[45]

CLINICAL PEARLS

Infections in Solid-Organ Transplant Recipients

- Most infections occur in the first 6 months following transplantation.
- In the first month, most infections are nosocomial or are related to surgical procedures or preexisting infection in the donor or recipient.
- Infections between 1 and 6 months following transplantation are commonly secondary to the use of immunosuppressive drugs, with a predominance of cytomegalovirus infection.
- Infections after 6 months are usually due either to chronic viral infection, acquired earlier, or to chronic allograft dysfunction, necessitating repeated courses of high-dose immunosuppression.

Infections in the First Month After Transplantation

Infections in this period are generally associated with technical complications of the surgery or have a nosocomial etiology. Donor-transmitted infections (*e.g.,* Chagas disease) or reactivation of prior infections (*e.g.,* colonization and infection with multidrug-resistant [MDR] bacteria) can also occur.[45]

Infections 1–6 Months After Transplantation

Before routine antimicrobial prophylaxis, this period was typically characterized by the presence of OIs, such as PJP and CMV infection; the incidence of these infections has been significantly reduced or delayed with TMP-SMX prophylaxis and CMV prophylactic or preemptive therapy. Reactivation of latent infections, such as TB, Chagas disease, endemic mycoses, and cryptococcosis, can occur. Viral infections, such as those with BK virus, adenovirus, RSV, HBV, and EBV, are common (Fig. 37.4). Invasive fungal infections, specifically *Aspergillus* and non-*Aspergillus* mold infections, can be problematic during this period of heightened immune suppression.[45]

Infections 6 Months After Transplantation

This period is less well defined; patients with satisfactory allograft function develop more severe manifestations of community-acquired infections but have a lower risk of OIs. Patients with poor allograft function and, therefore, increased immunosuppression or those with ongoing chronic viral reactivation are at high risk of OIs, such as invasive fungal infections, late-onset CMV infection, nocardiosis, PJP, listeriosis, and EBV-associated PTLD. In addition, lung transplant recipients with chronic graft dysfunction are at high risk of recurrent bacterial pneumonia. Similarly, liver transplant recipients with chronic graft dysfunction frequently develop biliary strictures and recurrent cholangitis.[45]

INFECTIONS IN HEMATOPOIETIC STEM CELL TRANSPLANTATION

Survival after HSCT has significantly improved during the last decade. Factors contributing to the increase in survival are the use of less toxic, nonmyeloablative conditioning regimens, use of peripheral blood stem cells (PBSCs) that leads to faster neutrophil recovery, and use of antimicrobial preventive therapies.[46] Despite these advances, infections are still a frequent cause of morbidity and mortality.

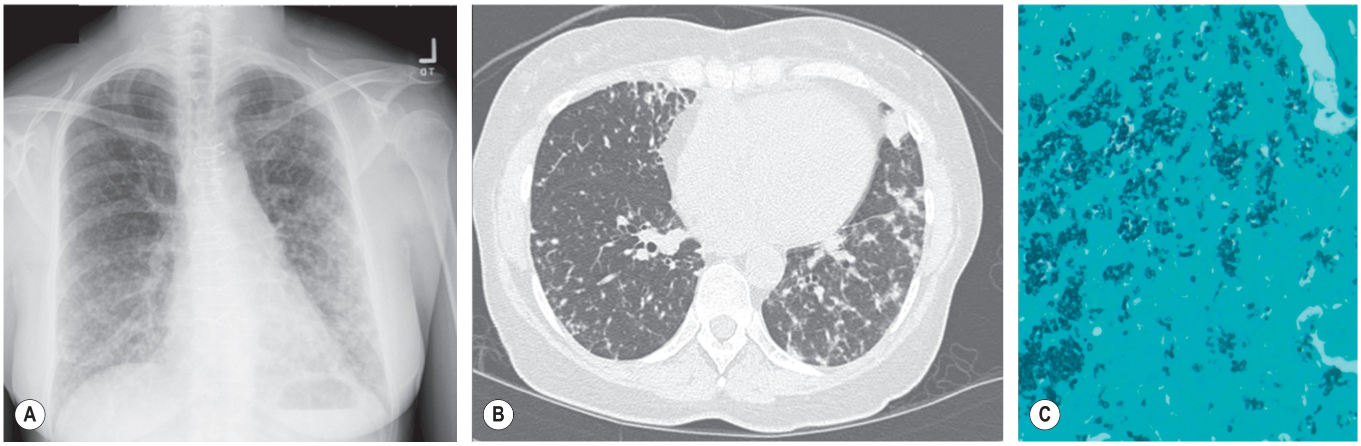

FIG 37.4 Disseminated Histoplasmosis in a Patient from an Endemic Area 3 Months After a Heart Transplantation. (A) Chest X-ray with bilateral reticulonodular infiltrates. (B) Computed tomography (CT) scan of the chest with bilateral patchy and nodular infiltrates. (C) Lung biopsy. Gomori methenamine silver (GMS) stain shows yeast forms compatible with *Histoplasma capsulatum.*

CLINICAL PEARLS

Infections in Bone Marrow Transplant Recipients

- Infections 2–4 weeks posttransplantation are usually caused by profound neutropenia and damage to mucosal surfaces.
- Between the period of engraftment and posttransplant weeks 15–20, OIs predominate and are commonly associated with the development of acute graft-versus-host disease (GvHD) and its treatment.
- Serious infections occurring 4–6 months following transplantation are seen predominantly in patients with chronic GvHD.

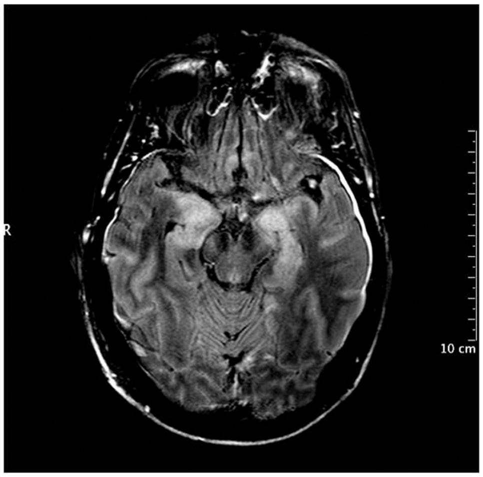

FIG 37.5 Magnetic resonance imaging (MRI) scan of the brain of a patient with human herpesvirus-6 (HHV-6) encephalitis 36 days after a matched unrelated donor hematopoietic stem cell transplantation (HSCT) for diffuse large B-cell lymphoma. Flair axial image shows bilateral medial temporal lobe edema compatible with limbic encephalitis.

The risk for infection is influenced by several factors and varies significantly between type of transplantation (autologous vs allogeneic), stem cell source (bone marrow, PBSC, and cord blood), degree of human leukocyte antigen (HLA) matching, hematopoietic potential of the graft (number of infused CD34$^+$ cells), T-cell depletion, type of conditioning (myeloablative vs reduced intensity vs nonmyeloablative), underlying disease, presence of graft rejection or GvHD, donor–recipient serological status to certain infections (*e.g.,* CMV infection), and use of antimicrobial prophylaxis.[47]

Autologous HSCT (auto-HSCT) refers to the patient serving as his or her own donor to allow administration of myeloablative chemotherapy. Because there is no risk of rejection or GvHD and because after engraftment there is an early and progressive recovery of cell-mediated immunity, the risk for infection is much lower than in allo-HSCT. The major compromises in host defenses occur before engraftment and are usually related to neutropenia and mucosal injury. In contrast, in allo-HSCT, the risk for infection can be divided into three periods: preengraftment, early postengraftment, and late postengraftment periods.

Preengraftment Period

The major impairments in host defenses before engraftment are neutropenia and mucosal injury. This period varies widely between different types of conditioning regimens and stem-cell source. In general, when ablative regimens are used, engraftment occurs any time between 15 and 45 days after transplantation and can be as short as 5–7 days with nonablative regimens.[47] PBSC grafts are associated with faster neutrophil engraftment compared with cord blood units and therefore lower rates of infection.[46] Bacterial infections are most common. However, when neutropenia is prolonged, the risk of invasive fungal infection increases significantly. Without acyclovir prophylaxis, reactivation of severe HSV infection is frequent.

Early Postengraftment Period

The resolution of neutropenia marks the beginning of this period and usually lasts 2–3 months (Fig. 37.5). This period is characterized by a progressive but slow recovery of B- and T-lymphocyte function; thus viral and fungal OIs can occur. The risk of infection is higher in patients who develop acute GvHD and therefore require high dose steroids. Common bacterial infections can still occur and are usually related to indwelling catheters or GvHD of the gut. CMV viremia is common during this period. However, routine use of preemptive or prophylactic therapy has been effective in preventing life-threatening CMV disease. The risk of *Pneumocystis* pneumonia (PCP) has also decreased since the introduction of PCP prophylaxis.[47]

Late Postengraftment Period

This is the period of late immune recovery and ends when the patient regains normal immunity. In the absence of chronic GvHD, this period can last up to 2 years. Viral and bacterial infections of the respiratory tract are common during this period. The development of chronic GvHD delays immune restoration and can extend this period for many years (as long as immunosuppressive drugs are required). Infections with encapsulated bacteria are common in patients with chronic GvHD, as well as opportunistic viral and fungal infections, including VZV and CMV infections, invasive aspergillosis and non-*Aspergillus* mold infections, and PJP, among others.[47]

INFECTIONS OF PARTICULAR IMPORTANCE IN TRANSPLANT RECIPIENTS

Cytomegalovirus Infection

CMV is one of the most important pathogens affecting transplant recipients. It is widely distributed in the general population; seropositivity for CMV varies in different geographical regions and ranges from 30% to 97%.[48] Before widespread use of interventions aimed at reducing the incidence of CMV disease (*i.e.,* pneumonitis, gastroenteritis, hepatitis, etc.), it occurred frequently during the first 3 months after transplantation. In SOT, the highest risk for CMV disease is in patients in whom the donor is seropositive and the recipient is seronegative for CMV (D^+/R^-). CMV has a predilection to invade the allograft, possibly as a result of an aberrant immune response within the graft. The risk of infection varies also with the type of transplantation; recipients of lung, small intestine, and pancreas transplants have a higher risk, whereas the risk in liver and kidney recipients is lower. In SOT, CMV infection has been found consistently to be an independent risk factor for other infectious complications as well as graft rejection.[48] In HSCT, infection is usually the result of reactivation of endogenous virus; hence the highest risk is in seropositive recipients. Without prophylaxis, up to 80% of seropositive recipients will experience CMV infection after HSCT. Seronegative individuals have a 30–40% chance of becoming infected when receiving unfiltered blood products or stem cells from a seropositive donor. Risk factors for CMV disease are acute and chronic GvHD, use of high-dose corticosteroids, use of cord blood, T-cell depletion, and use of mismatched or unrelated donors.[49]

Typically, CMV viremia precedes CMV disease by 1–2 weeks; therefore close monitoring of CMV reactivation by polymerase chain reaction (PCR) assays or pp65 antigenemia allows the detection of early replication, and therefore institution of appropriate antiviral therapy (ganciclovir, valganciclovir, or foscarnet) before the development of end organ disease. This approach, termed *preemptive therapy,* has the advantage of effectively decreasing the incidence of early CMV disease and limiting drug-related toxicities. In addition, a limited amount of viral replication may allow for the development of CMV-specific immune reconstitution. Preemptive therapy is the preferred method for preventing CMV disease in HSCT[49] and is widely used in SOT in patients with intermediate risk for CMV disease. In high-risk solid-organ recipients (D^+/R^-), in particular recipients of lung and small bowel, although preemptive therapy is an accepted alternative, universal prophylaxis is preferred. It has the theoretical advantage of preventing reactivation of other herpes viruses and may be more likely to prevent the indirect effects of CMV.[48,50] Recently, the development of commercially available CMV- specific IFN-γ release assays, which detect CMV-specific T cells in whole blood, may allow for more precise targeting of prophylactic strategies, beyond those currently used.[55]

Other Herpes Viruses

HSV infection is common in both SOT and HSCT recipients during the first month after transplantation. Routine use of antiviral prophylaxis has successfully decreased the incidence of severe HSV infection. However, breakthrough mucocutaneous HSV infection and even disseminated disease can still occur. Reactivation of VZV infection is also common; however, acyclovir prophylaxis has decreased the incidence of disseminated VZV infection significantly. Both severe VZV and HSV infections are typically treated with intravenous acyclovir.[45,46]

Although EBV can cause a wide spectrum of disease, EBV-associated PTLD is the most feared complication. The term *EBV-associated PTLD* is generally used to describe a heterogeneous group of clinical syndromes associated with uncontrolled lymphoproliferation, which can result in true malignancies containing clonal chromosomal abnormalities. Early diagnosis requires a high index of suspicion. EBV viral load monitoring and radiological evaluation can assist in early diagnosis. Reduction of immunosuppression should be the initial strategy in managing the disease. Timing of additional therapies, such as treatment with antivirals and rituximab and chemotherapy, remains controversial.[45,47]

HHV-6 has been associated with disease after transplantation, and although a variety of clinical manifestations have been described, the more convincing association is with encephalitis. The initial presentation may be subtle with memory loss or disorientation. However, it may progress to severe mental status abnormalities and seizures. The diagnosis is established with a positive PCR in the CSF, and absence of other infectious agents. Treatment is with ganciclovir or foscarnet.[47]

Invasive Filamentous Fungal Infections

Invasive pulmonary aspergillosis is the most common invasive filamentous fungal infection. Dissemination, including to the brain, can occur and should be ruled out in all transplant recipients. Risk factors are prolonged neutropenia, high-dose corticosteroids, cord blood transplantation, CMV disease, GvHD, graft rejection, and lung transplantation. Manifestations of filamentous fungi that are almost exclusively seen in lung transplant recipients are tracheobronchitis, characterized by ulceration and cartilage invasion, and bronchial anastomotic infections.[51]

Monitoring serum *Aspergillus* galactomannan in high-risk patients, as well as computed tomography (CT) imaging, can assist in the early diagnosis of invasive aspergillosis. Despite early diagnosis and treatment, the mortality associated with invasive aspergillosis, in particular in HSCT, is still high.[51] Antifungal prophylaxis should be considered in patients in whom prolonged neutropenia is expected, in patients with chronic GvHD receiving high-dose corticosteroids, and in lung transplant recipients. Voriconazole is considered the drug of choice for invasive aspergillosis, but newer-generation azoles, such as posaconazole and isavuconazole, are good alternatives.

Fusariosis, mucormycosis, and dematiaceous and other mold infections are increasingly recognized as significant pathogens in transplant recipients. Clinical disease can be similar to the infection caused by *Aspergillus* spp., with largely sinopulmonary disease. *Fusarium* spp. frequently disseminate hematogenously and can be isolated in blood cultures. Many of these infections are resistant to most antifungal drugs and remain an important cause of transplantation-related mortality.[51]

Invasive Candidiasis

Before routine use of antifungal prophylaxis, invasive candidiasis was the most common invasive fungal infection in transplant recipients. In SOT, most *Candida* infections occur during the first month after transplantation, usually related to the surgical procedure. Recipients of liver, pancreas, and small bowel are at high risk for invasive candidiasis; lung transplant recipients can develop bronchial anastomotic infections.[51] In HSCT, most *Candida* infections occur in the preengraftment period and are associated with mucosal injury, which results from the conditioning regimen and with the widespread use of antibiotics for the treatment of fever and neutropenia. Fluconazole-resistant *Candida* spp. are now increasingly isolated, and echinocandins (caspofungin, micafungin, and anidulafungin) are now considered the drugs of choice in invasive candidiasis.[52] Antifungal prophylaxis reduces the incidence of invasive fungal infections after HSCT, as well as infection-related and overall mortality. In SOT, antifungal prophylaxis is recommended for high-risk liver transplant recipients and in small bowel and lung transplant recipients.

TRANSLATIONAL RESEARCH

ON THE HORIZON

- Cytomegalovirus (CMV), Epstein-Barr virus (EBV), and adenovirus infections remain problematic infections in both hematopoietic-stem-cell and solid-organ transplant recipients, and medications currently available to treat these infections have significant associated toxicities or lack efficacy.
- Adoptive immunotherapy, in which virus specific donor-derived T cells are expanded and infused into the transplant recipient, will likely become more widespread in treating these infections.

Viral reactivation and disease are still a major cause of morbidity and mortality among transplant recipients. CMV, EBV, and adenovirus are particularly problematic once disease develops. Preemptive strategies have substantially decreased the incidence of invasive CMV disease; nevertheless, a significant number of patients still go on to develop invasive disease. Preemptive therapy and treatment are limited by the toxicity associated with the available antivirals and their lack of efficacy against EBV and adenovirus. In addition, development of resistance can complicate therapy. Development of new effective antivirals has been slow. Brincidofovir (CMX001) is an ether lipid ester analogue of cidofovir that has been reported to be 1000-fold more potent than cidofovir against DNA viruses, such as CMV and adenovirus. It is available in an oral formulation, but it lacks the nephrotoxic effects of cidofovir.[53] However, a recent trial in high-risk recipients in HSCT, in which brincidofovir was used to prevent CMV infection, did not achieve its primary endpoint for the prevention of clinically significant CMV infection after transplantation.[53] There are ongoing clinical trials to determine the efficacy and safety of brincidofovir for the treatment of other DNA viruses, such adenovirus and smallpox virus. Letermovir is a new, highly potent anti-CMV agent with a novel mechanism of action targeting the viral terminase subunit pUL56, a component of the terminase complex involved in viral DNA cleavage and packaging. Initial trials have shown that letermovir is effective in reducing the incidence of CMV infection in allo-HSCT and has been used successfully in MDR infections.[54] Phase III clinical trials are currently underway. There are other antivirals in the pipeline, but they are at much earlier stages of development. Because of the scarcity of effective, nontoxic antivirals and because uncontrolled viral infections correlate with a lack of cellular immunity against viruses, several groups are working on the development of adoptive immunotherapy, which is the artificial reconstitution of virus-specific T cells with *in vitro* expanded T cells.

A number of small studies have now shown that virus-specific T cells are effective in controlling CMV, EBV, and adenovirus infections in transplant recipients. The translation of adoptive immunotherapy into the clinic has been limited by technical difficulties associated with the generation of viral-specific cells that are not alloreactive, that can be produced from naïve T cells, and that can be developed rapidly and in a cost-effective way. Cells obtained from the original donor can yield long-lasting immunity, but the process of generating these cells can be cumbersome and often not available in a timely manner. Some groups have explored adoptive transfer of HLA partially matched virus-specific T cells derived from third-party donors, that is, healthy individuals other than the donor of the patient's transplant. Such cells yield high number of virus-specific T-cells, but these cells tend to be short lived.[55] Currently, a few international centers have established cryopreserved banks with virus-specific T-cell lines from normal donors, but these are still mostly for investigational use. Significant advances continue to be seen in the field of cellular therapy, and these could become part of the armamentarium against viruses in the next decade.

CONCLUSIONS

Immunocompromised hosts are surviving longer as antimicrobials improve and as immunosuppressant agents become less toxic. Both monogenetic primary immunodeficiencies and the increasingly specific immunosuppressant agents allow insight into host control of specific microbes. With this knowledge, new types of immunodeficiencies are being recognized, such as the autoantibody cytokine disorders described above. In addition, the knowledge of specific host immunity will help in developing therapies to boost host responses in the increasing challenges of treatment-resistant microbes.

MULTIPLE CHOICE QUESTIONS

1. Mucocutaneous candidiasis is thought to occur due to disruption of interleukin-17 (IL-17) signaling. This is observed in all of the following immunodeficiencies EXCEPT:
   - **A.** Loss of function mutations in signal transducer and activator of transcription 3 (STAT3) causing hyper IgE syndrome (HIES)
   - **B.** CD40 ligand deficiency
   - **C.** Gain-of-function (GOF) STAT1 mutations
   - **D.** Autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APOCED)

2. Anticytokine autoantibodies are increasingly being recognized as causing immunodeficiency. The following are described associations EXCEPT:
   - **A.** Anti-interferon (IFN)-γ antibodies and disseminated nontuberculous mycobacteria
   - **B.** Anti–GM-CSF antibodies and Cryptococcus
   - **C.** Anti-IL-17 antibodies and mucocutaneous Candida
   - **D.** Anti-IFNγ antibodies and *Staphylococcus aureus*
   - **E.** Anti–granulocyte macrophage–colony-stimulating factor (GM-CSF) antibodies and *Nocardia*

3. Progressive multifocal leukoencephalopathy has been described in the following settings EXCEPT:
   - **A.** Rituximab
   - **B.** GOF STAT1 mutations
   - **C.** Natalizumab
   - **D.** Chronic granulomatous disease (CGD)
   - **E.** Human immunodeficiency virus (HIV)
   - **F.** Dedicator of cytokinesis 8 (DOCK8) deficiency

4. Photosensitivity is associated with which antifungal?
   - **A.** Fluconazole
   - **B.** Caspofungin
   - **C.** Posaconazole
   - **D.** Voriconazole
   - **E.** Isavuconazole

Immune Deficiencies at the Extremes of Age

Jörg J. Goronzy, Claire E. Gustafson, Cornelia M. Weyand

Age is a major factor determining the quality and quantity of an immune response. This age dependency, apparent throughout life, is most obvious at the extremes of age. Both infants and older adults exhibit blunted immune responses to infections and vaccination. However, the underlying mechanisms for immune dysfunction are distinct. Infants are born with limited antigen exposure and an immature immune system, which, however, progressively develops throughout infancy and childhood. The mechanisms underlying the immune dysfunction in older adults are broadly termed *immunosenescence.* The term is reminiscent of *cellular senescence,* which is defined as the loss of the ability to proliferate as a result of an irreversible cell cycle block. However, it is misleading to interpret immune aging only as the accumulation of senescent cells, and similar to aging in general, numerous pathways are involved.[1] The decline in immune competence is not linear. As early as age 40 years, vaccine responses to selected vaccines (*e.g.*, hepatitis B) start to decline. The incidence rate of herpes zoster, a reactivation of latent varicella-zoster virus (VZV), starts to increase at age 50 years, as does morbidity and mortality from influenza infection. A more abrupt transition appears to occur in the eighth decade of life.

In terms of public health, infections are major causes of morbidity in the very young and the very old. Although child mortality rates have dropped by almost 50% between 1990 and 2013, pathogenic infections are still one of the largest causes of infant mortality worldwide, accounting for more than 1.6 million deaths a year. Vaccinations have helped change the infectious landscape in children and young adults, but certain vaccines, such as those against *Streptococcus pneumoniae,* still have limited protective capacity at both extremes of age. Susceptibility to pathogenic infection and ineffectiveness of vaccination is even greater in older adults than in young infants. Moreover, during aging, a functional immune system is important for tissue repair and is of increasing importance in degenerative diseases, and it is vital for cancer surveillance. Immunosenescence is of increasing importance because of the changing population demographics, with increases in the number of individuals older than 65 years in both developed and developing countries.

INFANCY AND THE GENERATION OF AN IMMUNE SYSTEM

Infants first start to develop their immune system *in utero,* maintaining a fine balance between immunological tolerance that helps prevent proinflammatory responses *in utero* and the ability to respond to foreign antigen exposure upon birth. Immunosuppressive regulatory pathways utilized by the fetus for protection against possible infections and maternal–fetal rejection *in utero* are still reflected in the newborn infant immune system, characterized by immune-suppressive, antiinflammatory, and immature cellular responses to foreign antigens. Although newborns and young infants lack the ability to mount effective immune responses against many pathogens, they acquire initial immune protection through the passive transfer of maternal immunoglobulin G (IgG) *in utero* via the placenta (termed "passive immunity")[2] and from secretory IgA and antimicrobial factors present in maternal breast milk. Alternations in passive immunity (*e.g.*, preterm birth) can lead to increased susceptibility to infections and breakdown of immune tolerance in the infant. Passive immunity can be enhanced by vaccination of pregnant mothers to promote the transfer of vaccine-specific IgG *in utero.* However, within the first months of life, as maternal IgG wanes and breastfeeding is discontinued, infants must actively develop their own innate and adaptive immune responses to initiate and maintain immune protection. An overview of the development of innate and adaptive cells, as well as the repertoire of diversity during aging, is outlined in Fig. 38.1.

INNATE IMMUNE DEVELOPMENT

The innate immune system is typically considered the first line of defense against infection. The development of the innate immune system begins *in utero,* with all the classic innate cells types present by the end of the first trimester; monocytes and dendritic cells (DCs) are the earliest cells observed at 4 weeks' gestation (WG) followed by granulocytes and natural killer (NK) cells at 8 WG.[3] These innate immune cells expand in number and mature during gestation; however, at birth the functionality of innate immune cells is still diminished significantly compared with later in life.

DYSFUNCTION OF INNATE IMMUNE CELLS

During early infancy, all cell types of the innate immune system demonstrate some impairment of function, ranging from reduced mobility to skewed cytokine production in response to innate immune stimulation. The most significant functional limitation of neonatal innate immune cells is their collective inability to kill pathogens. Limited chemotaxis in neutrophils is accompanied by a reduced ability to effectively kill pathogens as a result of poor phagocytosis and decreased secretion of neutrophil extracellular traps under inflammatory conditions, which in combination results in decreased killing of infectious pathogens. Moreover, NK cells and plasmacytoid DCs have reduced capacity to prevent

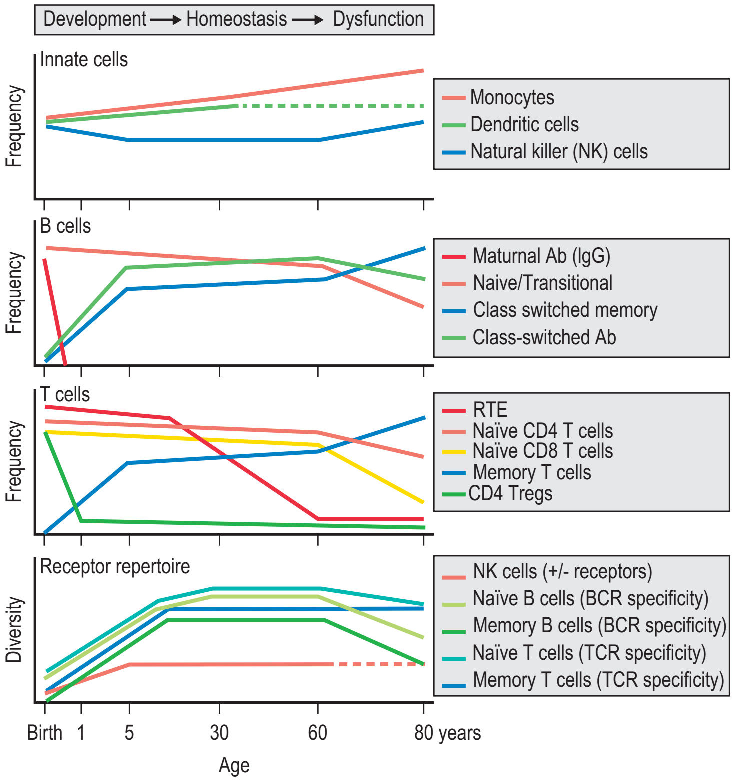

FIG 38.1 Innate and Adaptive Immune Cell Frequencies and Receptor Repertoire Diversity During Aging. The frequencies of different innate and adaptive B and T cells changes over the course of a lifetime (upper three panels). In addition to compartment size, diversity of antigen receptors is essential for immune function. During infancy, diversity of immune populations expands and is then maintained during adulthood (lower panel). Aging is characterized by the general decline in diversity within naïve B- and T-cell populations. Dotted lines indicate that the progression of these populations is either controversial or unknown.

infection through reduced cytotoxic function and lower secretion of interferon- (IFN-α), respectively. In addition, antigen-presenting cells (APCs) are unable to provide effective help to T cells because of reduced expression of costimulatory molecules and skewed cytokine production toward more antiinflammatory, T-helper 2 (Th2)–inducing cytokines, such as interleukin-6 (IL-6). These combined limitations during early infancy lead to increased susceptibility to viral and bacterial infections and also contribute to the reduced functionality of adaptive immune cells.

KEY CONCEPTS

Characteristics of the Developing Innate Immune System

- Reduced antibacterial responses (*i.e.*, phagocytosis, secretion of neutrophil extracellular traps [NETs]) by neutrophils and monocytes
- Impaired neutrophil chemokinesis ("directed movement")
- Diminished capacity of antigen-presenting cells (APCs; *i.e.*, dendritic cells [DCs]) to provide proper costimulatory help to T cells
- Reduced antiviral responses (*i.e.*, interferon (IFN)-α secretion) by plasmacytoid dendritic cells (pDCs)

ADAPTIVE IMMUNE DEVELOPMENT

Adaptive immune cells (T and B cells) begin to develop *in utero* around the start of the second trimester. It is important to note that although lymphocytes initially develop within the fetal liver (≈7 WG) and then in bone marrow (≈12 WG), T-cell maturation occurs in the thymus, and B cells continue maturation in bone marrow *in utero* and after birth. Over the course of gestation, both naïve T- cell and B-cell compartments expand, reaching absolute cell concentrations greater than that of the adults by birth. Thus a defect in cellular generation cannot account for the immune limitations observed in infants. However, the composition of the each lymphocyte population within young infants is distinct from that of adults. At birth, both the newborn infant T- and B-cell compartments consist mainly of naïve and immature cells recently migrated out of the thymus or bone marrow (>90% of the population). Both infant T- and B-cell repertoires have less diversity within their receptors' antigen-binding regions compared with those of adults. T-cell receptors display reduced V-J complexity and fewer amino acid additions. In addition, B cells have decreased B-cell receptor diversity because of less affinity maturation (*i.e.*, somatic hypermutation; Chapter 7) compared with adult populations.

The increased levels of recent thymic emigrants and naïve T cells are maintained both in the periphery and in tissues during early infancy. Effector memory T cells can be found selectively in the lungs and gastrointestinal (GI) tract of young infants, likely because these mucosal tissues are the earliest sites of antigen exposure. Class-switch antibodies produced by B cells are required for mucosal protection (primarily IgA) and systemic protection (primarily IgG) through opsonization, neutralization, or antibody-dependent cellular cytotoxicity (ADCC). However, infants demonstrate significantly lower levels of IgG and IgA compared with adults throughout the first year of life, in both the periphery and mucosae.

INFANCY AND FUNCTIONAL DIFFERENTIATION OF ADAPTIVE IMMUNE CELLS

The acquisition of a mature adaptive immune system requires exposure to antigens for cells to form immunological memory. Not only are infants born with limited antigen exposure and thus little memory, infant responses to antigenic stimulation in the T- and B-cell compartments display altered functions compared with that of adults. The most striking alterations are seen within the CD4 T-cell compartment, characterized by significantly increased frequency of immunosuppressive T regulatory cells (Tregs; 30–40% in infants vs 1–10% in adults).[4] These changes accompany increased Th2 subsets and defective differentiation to effector Th1 and T-follicular helper (Tfh) cells during early infancy. Moreover, decreased expression of Lck in infant CD4 T cells leads to decreased T-cell activation upon antigen exposure.[2] Altered differentiation of CD4 Th subsets and blunted T-cell activation promotes a tolerance-inducing environment good for controlling unnecessary responses to foreign antigen exposure after birth. However, it also leads to inhibition of effective cytotoxic T cells and limits B-cell antibody responses against infectious pathogens and to vaccination (Fig. 38.2).

The reduced antibody titers observed during infancy can be accounted for by the functional inability of infant B cells to undergo class-switching from IgM to IgA or IgG upon antigen stimulation[5] and the poor survival of antibody-secreting plasma cells within the infant bone marrow. Moreover, infant B cells have lower rates of somatic hypermutation compared with those of adults, which is important for affinity maturation and the generation of high-affinity antibodies. Although these defects can be partially attributed to extrinsic T-cell defects, such as poor Tfh generation, intrinsic defects in infant B cells (*e.g.*, lack of costimulatory molecules and receptors to T cell–independent factors) also prevent effective antibody responses. Collectively, these neonatal B-cell defects lead to less effective and shorter-lived antibody responses against infectious pathogens and vaccines during early infancy.

KEY CONCEPTS

Characteristics of the Developing Adaptive Immune System

- High frequencies of naïve and immature T and B cells
- Skewing of CD4 T-cell population towards immunosuppressive regulatory T cells and T-helper 2 (Th2) cells
- Reduced functionality and memory responses of CD8 T cells to viral infections
- Limited ability of B cells to produce high-affinity, class-switched antibodies in response to both T cell–dependent and T cell–independent antigens

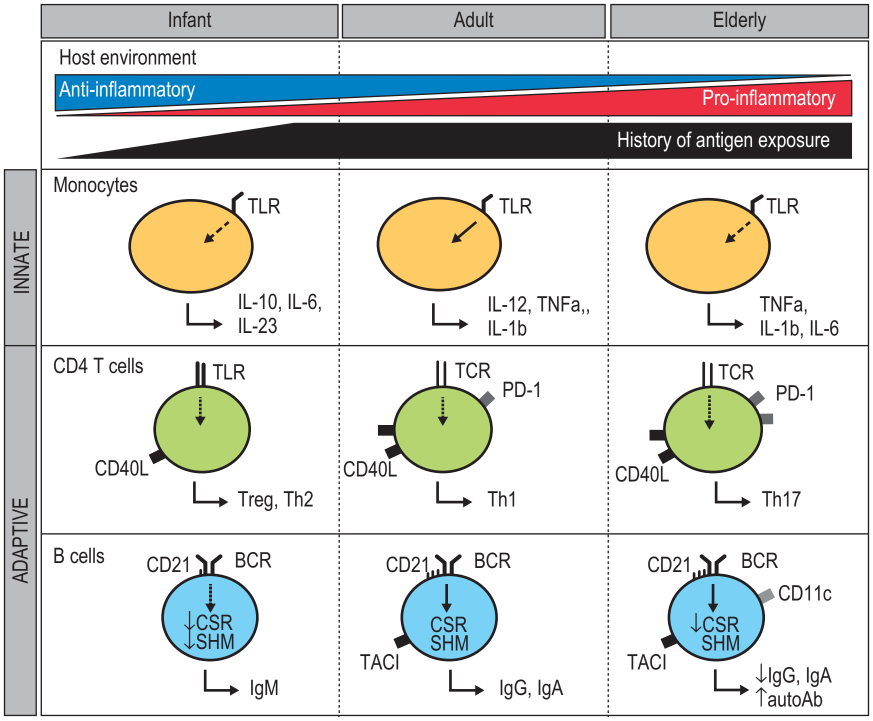

FIG 38.2 **Innate and Adaptive Immune Cell Functionality During Aging.** The infant immune environment is distinctly antiinflammatory characterized by altered Toll-like receptor (TLR) signaling from monocytes, blunted T-cell and B-cell receptor (TCR/BCR) signaling, and skewing toward T regulatory cells (Tregs). Infant B cells are incapable of class-switch recombination (CSR) or affinity maturation via somatic hypermutation (SHM) upon antigen exposure. Altered monocyte TLR signaling and altered function of adaptive immune cells is also observed in older adults, but with a distinct, more proinflammatory outcome.

INFANT IMMUNE DEVELOPMENT AND THE MICROBIOME

One of the first environmental exposures that infants experience is with colonizing bacteria. Within hours after birth, the infant intestinal tract is colonized with nonpathogenic bacteria (termed "microbiome"; Chapter 14). The microbiome can reach concentrations of 10^{10} bacteria per gram of stool by age 7 days, but only mirrors an adult-like composition after age 2 years. Early studies in animal models demonstrated that microbial colonization is essential for the normal development of the immune system during early infancy and throughout life.[6] In particular, IgA, the most abundant antibody within the GI tract, requires the presence of colonizing bacterial for its development and long-term maintenance. Moreover, the specific composition of the microbiome influences the generation of innate lymphoid cells, CD4 T-cells subsets (*e.g.,* Treg, Th17, Tfh), and antibody development. Perturbations in the infant microbiome, caused by such factors as mode of delivery, antibiotic treatment, and diet, may significantly alter developing immune responses.

It has been described that babies delivered via C-section have a microbiome composition distinct from vaginally delivered babies, the latter dominated by skin bacteria (e.g., Staphylococcus) instead of vaginal bacteria (e.g., Lactobacillus, Prevotella). These differences correlated with an increased incidence of allergy and asthma during childhood suggesting a causal link between microbiome and susceptibility to allergies. These findings are preliminary and more evidence is needed to support the notion that the microbiome influences the development of the infant immune system.

CLINICAL CONSEQUENCES FOR CHILDHOOD VACCINATION

Newborn and young infants are highly susceptible to pathogenic infection during the first months to year of life. Indeed, infections are one of the major causes mortality, accounting for more than 24% of global infant mortality. More than 1 million deaths per year are caused by respiratory tract infections (*e.g., Streptococcus pneumoniae, Haemophilus influenzae* type b, respiratory syncytial virus [RSV]) and almost the same amount by intestinal infections (*e.g.,* rotavirus, *Escherichia coli*). The development and distribution of vaccines targeting these pathogens have significantly reduced infant infection rates and subsequent mortality; however, vaccine efficacy can vary, depending on the infant's gestational age at birth, mode of vaccine delivery (oral vs intramuscular), interference by maternal antibodies acquired through passive immunity and via breast milk, and immaturity of infant immune responses, as described above. Additionally, infants require multiple vaccine boosters to elicit and maintain robust protective immunity against infectious pathogens (Chapter 90). Better understanding of the limitations of the human infant immune system that prevent effective immune responses, particularly at mucosal sites where these pathogens initially infect, would facilitate the generation of better vaccines designed to overcome these limitations and induce more rapid and robust immune protection during early infancy.

CLINICAL RELEVANCE

Consequences of Immaturity of the Developing Immune System

- Increased morbidity and mortality from bacterial infections (*e.g.,* pneumococci)
- Increased morbidity and mortality from viral infection (*e.g.,* influenza virus, respiratory syncytial virus [RSV])
- Ineffective primary vaccinations; multiple boosters required for most vaccines to elicit effective protection
- Susceptibility to allergy and asthma when microbiome colonization disrupted during early infancy

OLDER AGE AND IMMUNE CELL GENERATION

The immune system is in constant demand for cellular replenishment to compensate for peripheral losses and cell death. For neutrophils, which have a short half-life, the body needs to produce $\approx 10^{10}$ cells/kg per day. Additionally, for lymphocytes, which are more long-lived but are also more numerous because of their wider tissue distribution, the daily need is in the order of several billion cells. Studies in the 1960s showed that the hematopoietic tissue in bone marrow decreases with age. A similar decline is seen for the frequencies of peripheral CD34$^+$CD45$^+$ hematopoietic stem cells (HSCs). In addition to these numerical differences, the functional potential of HSCs changes with age.[7] Old HSCs exhibit a reduced capacity to regenerate the hematopoietic system. Telomerase expression in peripheral HSCs is not fully protective, and a shortening in telomeric length is seen with age, similar to differentiated mononuclear cells. Lymphoid differentiation potential diminishes with age in favor of myeloid differentiation as a result of altered lineage specification programs driven by DNA damage and epigenetic changes. This shift may contribute to the clinical observation that HSC-derived leukemia preferentially has a lymphoid phenotype in the young and a myeloid one in older adults.

KEY CONCEPTS

Aging Influences Immune Cell Generation and Population Homeostasis

Aging influences immune cell generation and population homeostasis.

- Hematopoietic stem cells (HSCs) are reduced in frequency and biased toward myeloid lineages and against lymphoid lineages.
- Myeloid cell generation is largely intact.
- B-cell generation declines and B-cell repertoire selection is disturbed.
- As a result of thymic involution, naïve T cells are generated from homeostatic proliferation of peripheral T cells.
- Ability to rebuild a T-cell repertoire after lymphocyte-depleting interventions is severely compromised after mid-adulthood.
- Virus-specific effector T-cell population accumulates.

As a consequence, lymphocyte replenishment is more affected by age than that of myeloid lineages. Peripheral neutrophil numbers do not decline and are able to recover after therapy-induced depletion (*e.g.,* chemotherapy). Furthermore, there is no loss in the ability to generate robust neutrophilia in response to infection or other stressors.

In addition to HSC-intrinsic alterations in lineage commitments, defects in bloodborne factors and bone marrow niches contribute to a decline in B-cell generation.[8] As a consequence, recovery after B-cell depletion (*e.g.,* treatment with anti-CD20 antibodies to treat B-cell malignancies or autoimmune diseases) is incomplete and delayed in older adults. Moreover, the frequency of typical memory B cells expressing CD27 declines, whereas other B-cell subpopulations increase. In particular, a functionally distinct B-cell population that responds to Toll-like receptor (TLR) stimulation has been described.[9] These age-associated differences in B-cell selection and expansion may contribute to monoclonal gammopathies (in >5% of individuals older than 70 years; Chapter 80) or increased autoantibodies with increasing age. High-throughput sequencing of Ig genes has the promise to provide insights into the age-associated decline in B-cell responses at the single-cell level. Data so far have indicated that older individuals have prevaccination-expanded B-cell populations that have a high mutation load and are further expanded with vaccination, suggesting that the B-cell response in older individuals relies on the adaptation of a restricted repertoire of memory sequences.

T-cell generation is more affected by age than any other myeloid or lymphoid lineage because of the involution of the thymus. The thymus undergoes dramatic structural changes that begin during childhood and puberty.[10] Thymopoietic niches disappear, and the numbers of thymic epithelial cells and thymocytes decline. In parallel, the thymic perivascular space increases. One major structural change that does not appear to be a compensatory response but, rather, is an active and regulated developmental step in thymic organ transformation is the accumulation and infiltration of adipocytes in the perivascular space. Thymic resection in children undergoing cardiac surgery reproduces many of the T-cell repertoire changes in 20-year-old individuals that are usually seen in 70- to 80-year-olds, confirming that thymic production during the growth period of childhood and adolescence is important. However, throughout adulthood, homeostatic proliferation of naïve T cells accounts for the bulk of T-cell generation.[11] For human CD4 T cells, this process is robust, and frequencies of naïve CD4 T cells only moderately decline with age. In contrast, the naïve CD8 T-cell compartment clearly shrinks. However, repertoire diversity (*i.e.,* the number of different T-cell receptors [TCRs]) remains very high for both naïve CD4 and CD8 T-cell subsets, suggesting that thymic activity is not necessary to prevent holes in the repertoire once a repertoire has formed. Strategies to reactivate thymic T-cell generation will be more important in older patients who cannot restore the naïve T-cell repertoire after a medical intervention, such as chemotherapy or bone marrow transplantation, compared with their healthy counterparts.

T-CELL POPULATION HOMEOSTASIS

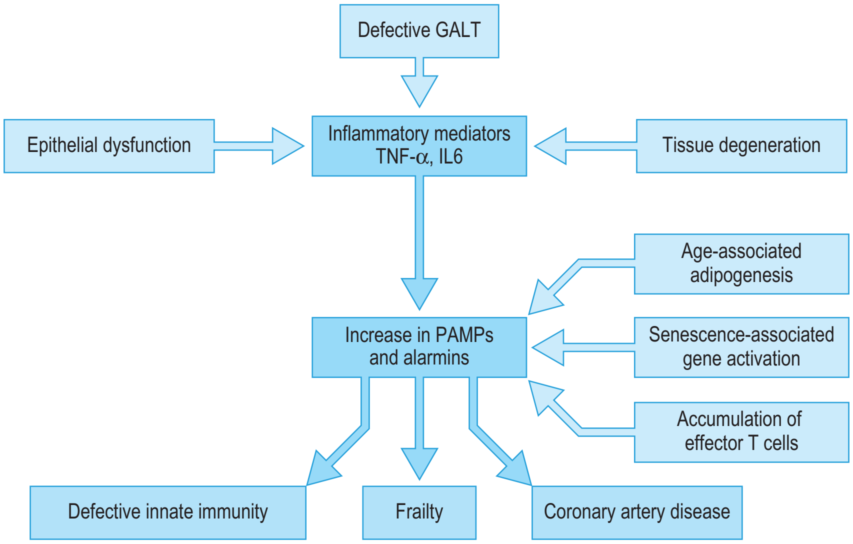
The adaptive system responds to antigenic challenges with clonal expansion and differentiation into effector cells followed by clonal downsizing and persistence of long-lived memory T cells. Infections therefore leave a permanent imprint on the immune system, a mechanism on which vaccinations capitalize. However, the pathogen-induced clonal expansion also represents a challenge to homeostatic mechanisms that are supposed to maintain a balance among naïve, memory, and effector cells.[12] This is particularly evident in persisting infections where the offending pathogen cannot be cleared. Herpes virus infections are highly prevalent in an apparently healthy population without causing active disease, as they establish latency. Classic examples are varicella-zoster virus (VZV), Epstein-Barr virus (EBV), and cytomegalovirus (CMV). The effects of these herpes viruses with immune aging differ greatly; VZV tends to relapse with age, with reactivation presenting as shingles. A decrease in the frequency of VZV-specific CD4 memory T cells has been postulated to explain this lack in viral control mechanisms. In contrast, EBV and CMV infections only relapse in severely immunocompromised individuals, but not during normal immune aging. The immune system commits extraordinary resources to controlling CMV, and CMV-specific CD8 T cells can make up a large fraction of the entire T-cell repertoire. Whether this memory inflation has broader implications for immune health remains a matter of controversy. Expansion of the CMV-specific T cells may compromise the size of naïve and central memory T cell repertoires; however, many of the CMV-specific CD8 T cells have the phenotype of end-differentiated effector T cells that lack the expression of CCR7, CD28, and CD27 and therefore do not compete for the same space as naïve cells.

$CD45RA^+CD28^-$ end-differentiated T cells express negative regulatory receptors of the killer lectin-like receptor (KLR), killer immunoglobulin-like receptor (KIR), and immunoglobulin-like transcript (ILT) families that appear to constrain their otherwise unopposed expansion. In spite of these inhibitory receptors, these cells are competent effector T cells capable of producing inflammatory cytokines and therefore possibly contributing to inflammation in older adults. End-differentiated $CD45RA^+$ effector T cells should be distinguished from exhausted CD8 T cells.[13] T-cell exhaustion is seen with chronic stimulation by highly replicating viruses or tumor cells and characterized by the expression of inhibitory receptors programmed death 1 (PD-1), T-cell immunoglobulin and mucin-domain containing-3 (TIM-3), and lymphocyte activation gene 3 (LAG3).[14] T-cell exhaustion is not a general feature *per se* of T-cell aging.

INFLAMMATION, AGING, AND THE AGING HOST ENVIRONMENT

The aging host environment is characterized by the continuous presence of inflammatory mediators independent of acute or chronic disease (Fig. 38.3).[15] Even for the healthy older adult, IL-6 and tumor necrosis factor (TNF) serum levels are twofold to fourfold higher than in young adults. Low-level systemic inflammation plays an important role in the progression of several age-related diseases, including Alzheimer disease, atherosclerosis, and cancer. Moreover, inflammatory markers are associated with several conditions that are characteristic of older adults. IL-6 serum concentrations have been correlated with loss of mobility and advent of disability; increased mortality of older individuals has been shown among those who have higher levels of TNF-α. Increased IL-6 and cross-reactive protein (CRP) serum levels and increased white blood cell (WBC) counts, presumably resulting from increased production of neutrophils, predispose to, and are associated with, frailty. A causative relationship may also exist between the increased production of IL-6 or TNF-α and the age-associated loss in muscle mass, eventually presenting as sarcopenia. Long-lived individuals, such as centenarians, tend to have lower levels of proinflammatory cytokines and increased levels of antiinflammatory mediators, such as cortisone and IL-10, supporting the concept that low-level inflammation is detrimental to healthy aging.

Production of inflammatory cytokines is driven by several mechanisms. Failure of the adaptive immune system leads to a less effective control of chronic viral infections as well as incomplete response to exogenous challenges, resulting in increased and prolonged innate immune activation. Defective epithelial barrier function, as well as decline in the mucosa-associated



Defective GALT
Epithelial dysfunction
Inflammatory mediators TNF-α, IL6
Tissue degeneration
Age-associated adipogenesis
Increase in PAMPs and alarmins
Senescence-associated gene activation
Accumulation of effector T cells
Defective innate immunity
Frailty
Coronary artery disease

FIG 38.3 **Inflammation in Older Adults.** The schematic diagram depicts possible mechanisms that account for the increased production of inflammatory mediators with age. These mediators contribute to many of the age-associated diseases.

lymphoreticular tissue (MALT), results in increased leakage and increased systemic levels of lipopolysaccharide (LPS) and innate immune activation. Failure in maintaining T-cell population homeostasis and accumulation of effector T cells also favors an inflammatory response.

KEY CONCEPTS

Causes for Increased Constitutive Production of Inflammatory Mediators With Age (Inflammation in Older Adults)

- Activation of the innate immune system as a result of defective epithelial barrier function
- Activation of the innate immune system as a result of defective adaptive immunity
- Accumulation of adipocytes producing inflammatory mediators
- Accumulation and activation of T-effector cell populations
- DNA damage-induced transcription of inflammatory cytokine genes in senescent cells

The immune system, however, is not the only source of inflammatory cytokines. Adipocytes, in part replacing muscle cells in older adults, produce various inflammatory mediators. Cellular senescence has also been associated with the production of cytokines. Persistent DNA damage response signaling not only induces an irreversible cell cycle block that is characteristic of cellular senescence but also initiates a transcriptional program to secrete numerous growth factors, proteases, and inflammatory cytokines, termed the *senescence-associated secretory phenotype* (SASP).[16]

CELLULAR DEFECTS AND SENESCENCE

As described so far, immune aging occurs at the system level with organizational restructuring. Equally important are changes at the single-cell level, which are partly cell-intrinsic and partly caused by the host environment. The increased cytokine concentrations in older adults not only activate but also attenuate signaling pathways. Low responsiveness to cytokine stimuli is frequently seen in those cells that have increased baseline activation of a signaling pathway (*e.g.,* cells that constitutively have increased signal transducer and activator of transcription 3 (STAT3) or STAT1 phosphorylation respond less to IL-6/granulocyte macrophage–colony-stimulating factor (GM-CSF) or type I/II IFNs, cytokines that activate these STATs). Attenuation of signaling pathways by induction of negative feedback loops explains, in part, the reduced responsiveness and functionality of cells of the innate immune system.

Although neutrophil and monocyte/macrophage numbers remain normal, many of their functions decline with age.[17] Decreased chemotaxis in neutrophils delays tissue infiltration; reduced phagocytosis and respiratory burst compromise the ability to control bacterial infections; and TLR-induced monocyte/macrophage activation is dampened in older adults. Declines in responsiveness, for example, to TLR stimulation, are partly reversible *in vitro,* suggesting that they are not intrinsic. Adaptive immune cells are also directly affected by the proinflammatory environment in the aging host.

Equally important are cell-intrinsic changes that appear to be a consequence of the replicative history and failures in cellular processes, such as DNA repair and autophagy. The program most obviously influenced by age is cellular senescence. In all hematopoietic cell lineages, including stem cells, telomeric lengths decline with age. This is of particular importance for T cells because much of their response depends on their ability to proliferate and clonally expand.[18] Telomeric erosion results not only from cumulative replicative history and DNA damage but also from decline in the ability to express telomerase and repair telomeric ends.

Lymphocytes in older adults are more differentiated than those in the young. Although most obvious for CD8 T cells, increasing differentiation can also be noted for B cells and CD4 T cells (Fig. 38.4). Differentiation is generally driven by antigen recognition but could also occur in the absence of exogenous antigen under the influence of cytokines. Proliferation alone may be sufficient to drive initial steps of differentiation. A classic

	Infant	Elderly

+ = low ++ = normal +++ = high *controversial

FIG 38.4 **Intrinsic Differences in CD4 T Cells at the Extremes of Age.** CD4 T cells from infants and older individuals demonstrate similar dysfunctions, including poor activation and reduced effector functions, although as a result of distinct mechanisms. Signaling cartoons illustrate the best documented defects. Moreover, infant and older adult T cells have very different internal changes to their DNA, including telomere length, the amount of DNA damage, and epigenetic modifications.

KEY CONCEPTS

Cellular Dysfunction With Age

- Exposure to aging host environment (*e.g.,* inflammatory cytokines) activates negative regulatory signaling loops.
- Telomeric erosion impairs proliferative competence and restraints clonal expansion.
- End-differentiation reduces functional plasticity.
- Activation of specific gene programs modifies cell function:
  - Gene programs associated with differentiation (*e.g.,* microRNA [miRNA])
  - Gene programs associated with T-cell exhaustion (*e.g.,* expression of programmed death-1 [PD-1])
  - Loss of CD28 on T cells
  - Gain in natural killer (NK) cell–associated regulatory receptors on T cells (*e.g.,* killer immunoglobulin-like receptor [(KIR], killer lectin-like receptor [KLR], immunoglobulin-like transcript [ILT])
  - Senescence-associated gene activation (*e.g.,* inflammatory mediators)

example is the acquisition of memory-like and effector phenotypes with lymphopenia-induced homeostatic proliferation. So-called virtual memory cells, which presumably have never seen an exogenous antigen, have been identified in mouse models; clonal expansions are also seen within the human naïve T-cell compartment. Some of the changes in gene expression that are seen in naïve T cells with age may represent partial differentiation, such as declines in the microRNA miR181a and changes in the expression of phosphatases and other signaling molecules.[18] Increased expression of cytoplasmic phosphatases impairs the TCR-induced activation of naïve T cells. Changes in cell surface molecules that are seen with terminal differentiation, such as the gain in CD57 and the loss of CD27 and CD28 expression, are the most striking. Of functional importance, predominantly for CD8 T cells, is the gain in expression of cell surface receptors that are usually only found in NK cells. Most of these receptors have inhibitory function, but some of them also stimulate. Since expression of these receptors on individual cells is stochastic, the consequences can range from immunosuppression to autoreactivity.

CLINICAL CONSEQUENCES OF IMMUNE AGING—IMMUNODEFICIENCY, AUTOIMMUNITY, AND ACCELERATED DEGENERATIVE DISEASES

The most profound and most noted consequence of human senescence is the increased susceptibility to infections. Upper respiratory bacterial and urinary tract infections are frequent in the older population and less contained by the innate immune system and preexisting adaptive immunity. Not surprisingly, the immune system of an older adult is not able to induce a protective response to new antigens to which the individual has not been exposed to in the past. Clinically important examples are the severe acute respiratory syndrome (SARS) epidemic and West Nile fever virus infection. First-time vaccinations with live viruses, for example, yellow fever virus, are associated with increased morbidity and even mortality in older adults. Despite annual vaccination, influenza infections continue to be associated with high morbidity and mortality. Pneumonia caused by RSV, usually infecting young children, is not uncommon. Immune competence to chronic infections is also compromised with age. The best example here is the reactivation of VZV manifesting as shingles.

CLINICAL RELEVANCE

Consequences of Immune Aging

- Increased morbidity and mortality from bacterial infections (*e.g.*, pneumococci)
- Increased morbidity and mortality from viral infections (*e.g.*, influenza, West Nile fever)
- Reactivation of latent virus (*e.g.*, varicella zoster virus)
- Ineffective primary and booster vaccinations
- Acceleration of degenerative diseases as a result of the production of inflammatory mediators (*e.g.*, atherosclerotic disease, Alzheimer disease, osteoarthritis)
- Increased incidence of autoimmune disease (*e.g.*, polymyalgia rheumatica, giant cell arteritis, rheumatoid arthritis)

Vaccinations against pneumococcal antigens, influenza strains, and VZV are recommended in older adults; however, the efficacy of vaccination is reduced.

Immune aging also predisposes for autoimmune manifestations and a breakdown in self-tolerance.[19] Autoantibodies are a common finding in healthy older adults; many of these autoantibodies are specific for common autoantigens, such as IgG Fc or nuclear components. The risk for several autoimmune diseases, most notably polymyalgia rheumatica and giant cell arteritis, increases with age. Although polymyalgia rheumatica predominantly presents as an activation of innate immunity, giant cell arteritis is clearly a disease of the adaptive immune system with T cell–dependent granulomatous inflammation in the vascular wall of midsized and large arteries.

The low-grade inflammation in the aging host has direct clinical consequences in promoting frailty and sarcopenia and accelerating degenerative diseases, including coronary artery disease, osteopenia, and Alzheimer disease. Accelerated immune aging may be one of the reasons that autoimmune diseases, such as rheumatoid arthritis (RA), are associated with a shorter life span and increased risk for cardiovascular morbidity. Inflammation as a manifestation of accelerated aging has been also implicated in the increased morbidity and mortality of patients with HIV infection in spite of highly active antiretroviral therapy (HAART).[20]

STRATEGIES AND INTERVENTIONS ON THE HORIZON

Vaccinations hold the promise for reducing increased susceptibility to infections in young children and older adults, but improving vaccine responses has proven to be a challenge. Current strategies for targeting more elusive pediatric pathogens (*e.g.,* RSV) included maternal vaccination (*i.e.,* the mother is vaccinated during pregnancy and vaccine-specific IgG is transferred *in utero* to the infant) and the development of infant-specific vaccine adjuvants utilizing newer understanding of the developing infant immune system. Also, further investigations into the role of microbiome and immune development (or dysfunction) may open new strategies to influence immune system development to reduce immune deficiencies and prevent inappropriate hyperactivity.

In older adults, a proper T-cell response to infectious organisms or to vaccines depends on the availability of a T-cell repertoire that includes antigen-receptor specificities to respond to vaccination. Repertoire contraction resulting from thymic involution or memory inflation appears to be less severe than originally thought, and currently explored interventions to restore thymic activity may only be meaningful for selected populations, such as bone marrow recipients. Deficiency in the antigen-presenting system and in costimulatory signals may be overcome by identifying new adjuvants. Increasing the vaccine dose is another promising approach. Live vaccines or self-replicating constructs that also accomplish higher antigen loads may not have a sufficient safety profile in older adults. Direct targeting of signaling defects in older T cells resulting from increased expression of cytoplasmic phosphatases or inhibitory cell surface receptors will be feasible, as shown for checkpoint inhibitors in oncology; however, such approaches need to demonstrate a much better safety profile.

Interventions to influence inflammation in older adults at present needs to be nonspecific, given the multitude of underlying mechanisms. Immunomodulatory therapy is obviously standard practice in patients with autoimmune disease who exhibit accelerated aging and increased all-cause mortality. Calorie restriction to slow immune aging to an extent that it is effective is generally not well accepted. Statins and aspirin are being routinely used to prevent cardiovascular disease; their effect may be mostly antiinflammatory. Future interventions will require the development of mild and low-toxicity medications to reduce low-grade inflammation while not impairing the ability to prevent innate immune activation in response to harmful antigens.

ON THE HORIZON

- Improved vaccination strategies tailored to the infant or aged immune system (novel adjuvants, novel vaccine delivery systems)
- New vaccines for pregnant females to confer passive immunity
- Manipulation of the microbiome composition to influence immune system development
- Thymic rejuvenation (*e.g.* with KGF, IL-7 and other mediators)
- Prevention of chronic infection that accelerate immune aging (*e.g.* immunization for CMV)
- Pharmacological approaches to improve T and B cell activation, clonal expansion and differentiation
- Treatment of inflamm-aging

MULTIPLE-CHOICE QUESTIONS

1. The developing immune system is characterized by:
   A. Increased frequencies of regulatory T cells.
   B. Innate immune system activation.
   C. Frequent presence of autoantibodies caused by tolerance defects.
   D. Hematopoietic stem cells preferentially differentiating into myeloid and not lymphoid lineages.

2. An inflammatory environment in older adults is:
   A. Less pronounced in frail older adults.
   B. Caused by thymic involution.
   C. Characterized by the production of cytokines from various cell types.
   D. Results from failure of naïve T cells to differentiate.

3. The following consideration to vaccinations in older individuals is correct:
   A. Annual influenza vaccinations are not always protective and are therefore not recommended in older individuals.
   B. Vaccinations with live viruses (*e.g.*, yellow fever vaccine) are potentially harmful.
   C. Only booster, but not primary, vaccine responses are impaired in older individuals.
   D. Vaccinations even with inactivated or component vaccine carry a higher risk in older adults.

4. T cells are derived from hematopoietic stem cells that differentiate in the thymus. Which of the following statements is correct?
   A. Thymic involution leads to a rapid loss of naïve T cells.
   B. Upon thymic involution, peripheral homeostatic proliferation of existing T cells to is effective to at least partially compensate for T cell loss.
   C. The thymus starts to involute after the age of 50 years.
   D. Generation of T cells by homeostatic proliferation can increase the T-cell receptor repertoire.

Human Immunodeficiency Virus Infection and Acquired Immunodeficiency Syndrome

Susan L. Gillespie, Javier Chinen, Mary E. Paul, William T. Shearer

In recent years, there has been a stabilization and possible reversal of the overall growth of the global acquired immunodeficiency syndrome (AIDS) epidemic. The number of new infections has steadily declined since the late 1990s, and there are fewer AIDS-related deaths as a result of the scale-up of antiretroviral therapy (ART) since 2004. People living with human immunodeficiency virus (HIV) are now living longer and healthier lives.

According to the Joint United Nations Programme on HIV/AIDS (UNAIDS), 36.9 million people worldwide were estimated to be living with HIV or AIDS at the end of 2014 (Fig. 39.1).[1] New HIV infections are declining in most countries. The annual number of incident HIV infections peaked at >3 million in the late 1990s and has steadily declined thereafter. In 2014, 2 million people were newly infected, with approximately 1% of these infections (220 000 cases) occurring in children younger than 15 years of age.[1] Globally, however, adolescents, particularly adolescent girls, are at particular risk for acquiring HIV infection. In 2012, there were 300 000 new infections reported among adolescents aged 15–19 years, which accounted for about 13% of all new infections. In sub-Saharan Africa, 70% of new infections in adolescents occurred among girls.[2] There has been a slow but continued reduction in the number of people dying from AIDS-related conditions worldwide. AIDS mortality peaked at 2.1 million in 2004, and by the end of 2014, it was down to 1.2 million deaths resulting from AIDS-related illnesses.[1] The decline reflects increased access to ART and improvements in the care and support of infected individuals. Mortality among children younger than 15 years of age has also declined as a result of the expansion of services to prevent mother-to-infant transmission of HIV and an increase in access to care and treatment for children. Although access to care and treatment services for HIV-infected children in resource-limited settings is expanding, it is estimated that only 31% of children in need of life-saving ART received it, and an estimated 150 000 children had died of AIDS-related illnesses in 2014. Of concern, HIV/AIDS is the most common cause of death among adolescents in sub-Saharan Africa and the second leading cause of death among adolescents globally.

US Perspective

The Centers for Disease Control and Prevention (CDC) estimate that almost 1.2 million adults and adolescents were living with HIV in the United States at the end of 2014, including 156 300 (12.8%) whose infection was undiagnosed. Despite ongoing prevention efforts designed to reduce the number of new cases of HIV infection, the number of newly diagnosed infections in the United States has remained unchanged from 2006–14, approximately 40 000–50 000 per year. Within the United States, there is great variability in both the geographical and demographic distribution of the disease, with certain segments of the American population being disproportionately affected, specifically men who have sex with men (MSM) and ethnic and racial minorities, including African Americans and Hispanic Americans (Fig. 39.2).[3] In the United States and other developed countries, in contrast to more resource-limited parts of the world, the number of children newly infected with HIV has decreased dramatically as a consequence of successful interventions against perinatal mother-to-child transmission. In 2014, 174 children were diagnosed with HIV infection, 73% of whom had acquired the infection through perinatal transmission.[4] At the same time, new pediatric AIDS cases and AIDS deaths also have plummeted, in large part as a result of powerful combinations of antiretroviral (ARV) drugs.

KEY CONCEPTS

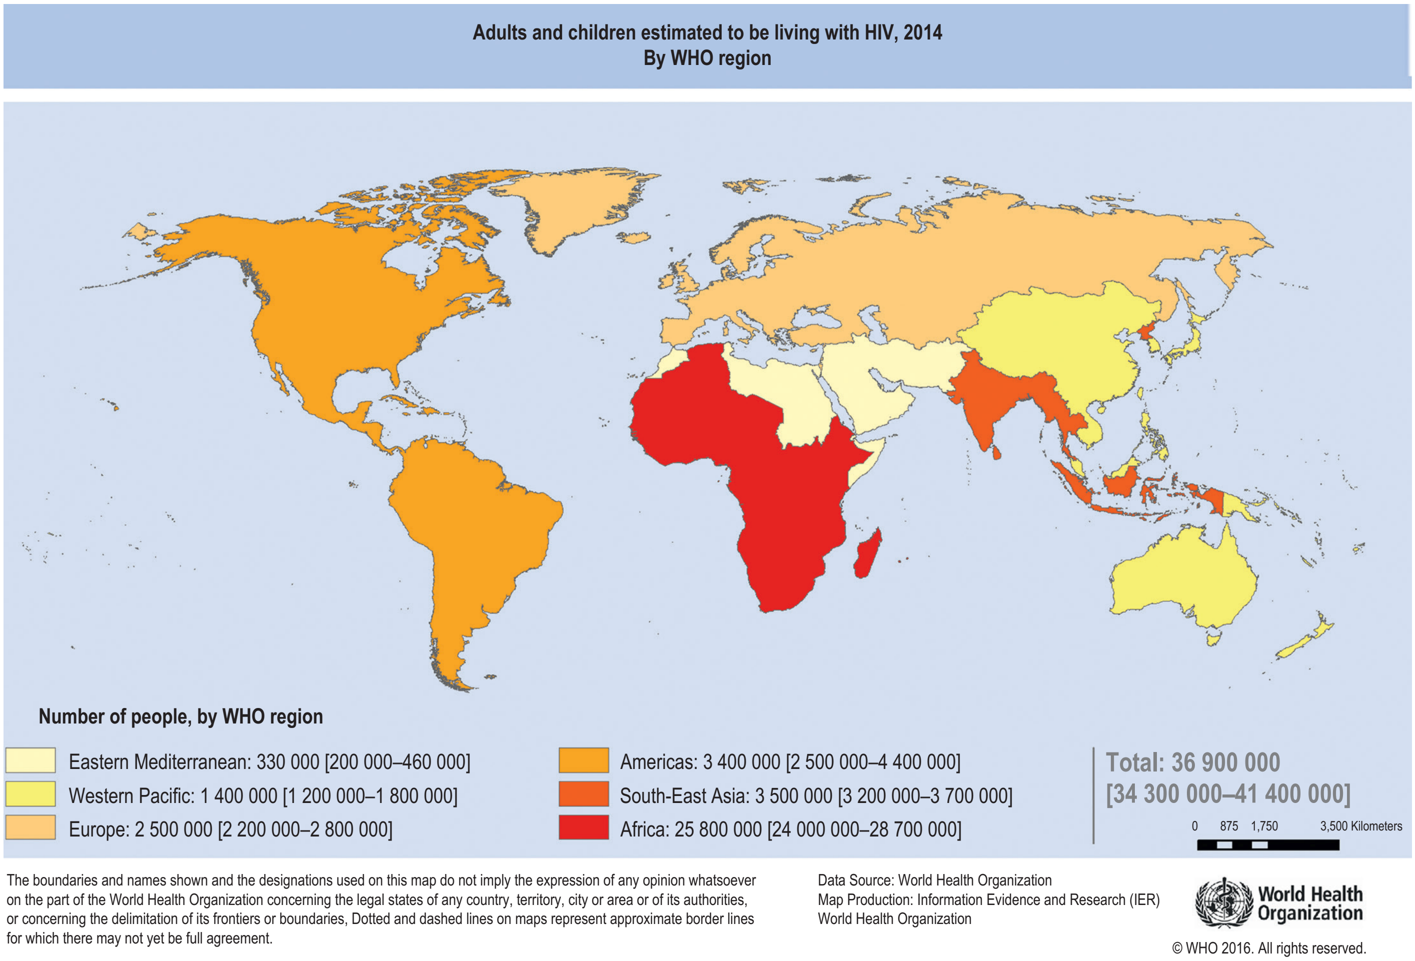
Trends in Human Immunodeficiency Virus (HIV) Infection

- Global rates of HIV infection have stabilized, but there is great heterogeneity in disease incidence among countries and regions.
- Although most countries had a reduction in disease incidence between 2001 and 2009, seven countries had increases in disease incidence by more than 25% over that period.
- The age demographic most affected in the developing world, that is, those aged 25–44 years, includes men and women who are economically productive and women of childbearing potential.
- Worldwide, most infections are acquired through heterosexual contact.
- In the United States, African Americans and men who have sex with men (MSM) are disproportionately infected.
- The numbers of infections transmitted from mother to child are declining as access to prophylactic medications to prevent infection improves.

HIV PATHOGENESIS

HIV Lifecycle

HIV is a lentivirus that targets CD4 T cells by specifically binding the viral Env protein to two cell surface proteins, the CD4 receptor, and either the CCR5 or the CXCR4 chemokine receptor (Fig. 39.3). Other cell targets for HIV are monocytes and dendritic cells (DCs), although they present less expression



Adults and children estimated to be living with HIV, 2014
By WHO region
Number of people, by WHO region
Eastern Mediterranean: 330 000 [200 000–460 000]
Western Pacific: 1 400 000 [1 200 000–1 800 000]
Europe: 2 500 000 [2 200 000–2 800 000]
Americas: 3 400 000 [2 500 000–4 400 000]
South-East Asia: 3 500 000 [3 200 000–3 700 000]

The HIV Life Cycle

HIV medicines in six drug classes stop HIV at different stages in the HIV life cycle

① **Binding (also called attachment):** HIV binds (attaches itself) to receptors on the surface of a CD4 cell.

✗ CCR5 antagonist

② **Fusion:** The HIV envelope and the CD4 cell membrane fuse (join together), which allows HIV to enter the CD4 cell.

✗ Fusion inhibitors

③ **Reverse transcription:** Inside the CD4 cell, HIV releases and uses reverse transcriptase (an HIV enzyme) to convert its genetic material– HIV RNA– into HIV DNA. The conversion of HIV RNA to HIV DNA allows HIV to enter the CD4 cell nucleus and combine with the cell's genetic material– cell DNA.

✗ Non-nucleotide reverse transcriptase inhibitors (NNRTIs)
Nucleotide reverse transcriptase inhibitors (NRTIs)

④ **Integration:** Inside the CD4 cell nucleus, HIV releases integrase (an HIV enzyme). HIV uses integrase to insert (integrate) its viral DNA into the DNA of the CD4 cell.

✗ Integrase inhibitors

⑤ **Replication:** Once integrated into the CD4 cell DNA, HIV begins to use the machinery of the CD4 cell to make long chains of HIV proteins. The protein chains are the building blocks for more HIV.

⑥ **Assembly:** New HIV proteins and HIV RNA move to the surface of the cell and assemble into immature (noninfectious) HIV.

⑦ **Budding:** Newly formed immature (noninfectious) HIV pushes itself out of the host CD4 cell. The new HIV releases protease (an HIV enzyme). Protease acts to break up the long protein chains that form the immature virus. The smaller HIV proteins combine to form mature (infectious) HIV.

✗ Protease inhibitors (PIs)

FIG 39.3 The human immunodeficiency virus (HIV) lifecycle and stage susceptibility to antiretroviral therapy. (From https://www.aidsinfo.nih.gov/education-materials/fact-sheets/19/73/the-hiv-life-cycle.)

of these receptors compared with CD4 T cells. After the virus is attached to the cell, the viral membrane fuses with the cell membrane and viral RNA enters the cytoplasm. It is transcribed by the viral reverse transcriptase into double-stranded DNA, which is translocated to the cell nucleus, and the virus integrase enzyme mediates its integration into the cell genome. The viral proteins Tat and Nef, in addition to T-cell activation factors, induce active transcription and expression of viral RNA and proteins to produce new virus particles that exit the host cell to infect other cells. CD4-independent viral entry has been demonstrated in B cells, astrocytes, and kidney epithelial cells; however, efficient viral replication is not likely to occur in these cells (see Treatment).

HIV Entry Through Mucosal Surfaces

Using dilution techniques that can precisely determine unique virion genome sequences, it was found that about 80% of HIV infections via heterosexual transmission start with a single virion.[5] This is remarkable, considering the high rate of mutation and diversity of viral genome sequences found in infected individuals. In contrast, HIV transmission occurring in MSM and in intravenous drug users is caused by several viral variants, indicating that the multilayered epithelia of the vaginal mucosa and the cervical mucus are likely deterrents for lentiviral infection.[6] Regardless of the route of infection, the time to develop viremia and immunological changes is similar to that of all forms of transmission. Viral replication can be detected in the germinal center of lymph nodes within a week, and viremia is found within 21 days of infection. The most active replication occurs in the gut-associated lymphoid tissue (GALT), with massive depletion of CD4 T cells. Activation and destruction of CD4 T cells are associated with an increase of serum cytokines, which might explain the flu-like syndrome that patients might experience during acute HIV infection.[7] Simultaneously, HIV reservoirs become established with viral infection and integration of viral DNA in resting cells.

T-cell Depletion

Progressive T-cell depletion in HIV infection is induced, in part, by a state of chronic immune activation, which also contributes to noninfectious complications, such as cardiovascular disease.[7] In individuals with HIV infection, immune activation is caused by increased microbial translocation in the gut, direct Toll-like receptor (TLR) stimulation by HIV, and coinfection with other pathogens. This activated state results in increased levels of inflammatory cytokines, such as interleukin-6 (IL-6). Also detected is an increase of lipopolysaccharide (LPS) in blood, which, in turn, can also activate the coagulation cascade and promote thrombosis. Low or normal levels of T regulatory cells (Tregs) are observed in long-term nonprogressors, suggesting their role in anti-HIV immunity, especially in modulating CD8 T-cell immunity. It has also been suggested that Tregs may play a beneficial role by reducing chronic immune activation.[8]

HIV Latency and HIV Reservoirs

The most difficult problem in the efforts toward achieving a cure for HIV infection is the presence of *HIV reservoirs*, defined as resting or nonreplicating cells infected with HIV.[9] Anti HIV drugs are able to efficiently suppress HIV replication; however, when these drugs are stopped, activation of the resting cells results in the production of new virus. Most viral DNA is detected in memory CD4 T cells within lymphoid tissues and peripheral blood. They might produce very low levels of viral RNA and proteins and therefore might not be detected by immunosurveillance. HIV reservoirs are established during the acute phase of the infection, hence the recommendation for early intensive treatment to reduce the population of latently infected CD4 T cells (nonreplicating monocytes, astrocytes, and glial cells are other latently infected cells). Molecular mechanisms that inhibit HIV replication from viral DNA and maintain latent infection include histone deacetylases and methyl transferases with methylation of viral genes, especially of the long-terminal promoter repeat. These epigenetic modifications can be reversed by using T-cell activation signals.

ANTI-HIV IMMUNITY

Immunity against HIV depends mostly on specific cytotoxic CD8 T cells, which recognize and destroy infected cells.[7] These antiviral cells are most efficient when certain combinations of human leukocyte antigen (HLA) and virus strain occur in the host, such as the presence of a cell bearing the HLA-B27 allele and infected with clade B viral strain. However, HIV infection almost always results in global T-cell destruction and exhaustion. Antibody responses are initially directed against the gp41 portion of the Env protein. This response and subsequent anti-HIV antibodies become ineffective because of the rapid production of escape mutants.

HIV Vaccines: Basic Concepts

Several efforts to develop an effective anti-HIV vaccine have attempted to address the genetic diversity of HIV that develops in the infected individual, by identifying epitopes that remain relatively conserved and by inducing neutralizing antibodies as well as cell-mediated immunity.[10] Broadly neutralizing antibodies, which target conserved Env epitopes from different strains and can prevent HIV from establishing infection, might develop in some individuals with chronic infection, offering hope for disease prevention. Such antibodies are found to develop after approximately 2 years of infection, when many generations of escape virions, inducing new antibody epitopes, allow the immune response to refine and select for best affinity. This concept suggests that several booster immunizations might reproduce the process in shorter time. Current approaches involve viral vectors that drive the expression of HIV proteins in host tissue; an example is a canary pox virus carrying the HIV *env* gene. No current vaccines have been able to induce high titers of broadly neutralizing antibodies against HIV Env. Of note, an unexpected, although modest, increased rate of HIV infection was observed in individuals immunized with an adenovirus-based HIV vaccine compared with nonimmunized individuals and was highest in persons who had antiadenovirus antibodies before the trial. The mechanisms explaining this increased infection rate are not clear. Results from the RV144 clinical trial conducted in Thailand showing a 31% reduction of HIV transmission demonstrated that vaccine protection may be a reality. New vector approaches, improving T-cell responses and achieving high titers of broadly neutralizing vaccines, are being investigated to increase vaccine efficacy (see HIV preventive vaccines).

ROUTES OF INFECTION

HIV is transmitted through three routes of infection: sexual, parenteral, and perinatal. In general, higher viral loads, lower

CD4 T-cell count, and larger viral inoculum size are all associated with a greater risk of transmission.

Sexual transmission is the most common mode of infection, responsible for 70–80% of worldwide infections. Besides the factors mentioned above, recipients in penetrative intercourse are more likely to become infected. Anal intercourse carries the greatest risk, followed by vaginal intercourse, and oral intercourse is the least likely to spread the virus. The presence of other sexually transmitted diseases, especially ulcerative lesions, such as those seen in herpes simplex or syphilis infection, increases the risk of transmission.

Parenteral transmission is the second most common route of HIV infection, accounting for 8–15% of all HIV infections. Examples include contaminated needles used by people who are addicted to intravenous drug use (IDU), accidental needle sticks occurring in health care workers, improperly sterilized hospital equipment, and contaminated blood products. Use of contaminated needles by people addicted to IDU is the largest risk factor for parenteral transmission. In 2013, 7% of the estimated 47 500 new HIV infections in the United States were attributed to IDU.[11] Although infection control efforts have greatly reduced the risk, HIV transmission via transfusion of contaminated blood products remains significant, particularly in resource-limited settings where there is a dependence on replacement of blood by family member donors and paid blood donors and where the infrastructure for routine blood screening is suboptimal.

Perinatal transmission accounts for the majority of pediatric HIV cases and for 5–10% of HIV infections in patients of all ages. The virus is capable of infecting the child *in utero*, during labor, and after delivery through breastfeeding. Without preventive therapy, the risk of a child contracting HIV from the mother during gestation or during labor is about 15–40%. The majority of transmission events occur during the passage of the fetus through the birth canal, by exposure of the baby to infected maternal blood, amniotic fluid, and/or cervical and vaginal secretions.[12] Although breastfeeding increases the risk of transmission of the virus from mother to child by another 15–29%, breastfeeding is still recommended to prevent morbidity and mortality related to diarrheal diseases in settings where access to replacement feeding is limited.

IMMUNOPATHOGENESIS

The mechanisms of immunodeficiency induced by HIV are not limited to depletion of its main target cell, the CD4 T cell; HIV infection ultimately leads directly or indirectly to the impairment of every arm of the immune system.[6] The time of progression from infection to the development of AIDS is not the same for all infected individuals, and several explanations have been proposed, including genetic resistance genes and the presence of low-virulence mutant viral particles. The study of long-term nonprogressor individuals has helped to define T-cell and antibody features associated with anti-HIV immunity in the search for the optimal vaccine design, focusing on minimizing the escape variants and inducing persistent specific viral neutralization or inhibition of replication.[10] HIV researchers have also explored the role of chronic immune activation processes that are associated with progression to AIDS, which also helps explain the diverse clinical impact of this viral infection in different individuals.

Mucosal Dendritic Cells: Myeloid Versus Plasmacytoid

Following a mucosal inoculation of HIV, CD4 T cells are generally infected by CCR5-tropic virus, also called *R5* or *M-tropic virus.*[13] After approximately 1 week, the virus becomes detectable in draining regional lymph nodes. Myeloid DCs are not infected with HIV; rather, HIV gp120 binds to DC-specific intercellular adhesion molecule–grabbing nonintegrin (DC-SIGN) in the cell membrane. The resulting complex is internalized as a phagosome and then presented on the cell surface. As there is no fusion of the HIV Env with the DC membrane, infection does not occur. Plasmacytoid DCs, in contrast, express CD4 and the coreceptors CXCR4 and CCR5 and thus become infected by the virus. Infection leads to expression of CCR7, which acts as a homing signal for the lymph nodes; it is in lymph nodes that the virus infects CD4 T cells, and significant viral replication occurs, resulting in detectable viremia and dissemination through lymphoid tissues. Of interest, the target cells for HIV infection, CD4 T cells and monocyte/macrophage cells, are also reservoirs for the virus. HIV-infected cells carry a stable provirus integrated in the cell genome, which is transcriptionally silent until the cell is activated. These cells can reestablish HIV viremia even after prolonged antiviral treatment, since viral reservoirs are unlikely to be soon eradicated.

Gastrointestinal System: Early Target

Within days of infection, 20% of CD4 T cells found in the GALT are infected. Of these, up to 80% are killed, by lytic infection and Fas-mediated apoptosis of both infected and noninfected cells, mainly $CD4^+CCR5^+$ memory T cells. By the time of peak viremia, 60% of the mucosal memory CD4 T cells are infected. Because their destruction is less drastic, circulating CD4 T-cell counts do not reflect the magnitude of CD4 T-cell death taking place in the GALT. Following acute HIV infection, a massive activation of the immune system occurs. Inadequate memory T-cell responses can lead to infection and inflammation of the entire bowel. The presence of immune activators over the massive surface area of the bowel has been hypothesized to result in the profound immune activation seen in HIV. Mucosal Th17 cells are a preferential target for HIV, further weakening mucosal immunity and favoring microbial infection. The viremia decreases spontaneously from as high as 10 million copies of HIV RNA per milliliter during the acute illness phase to a stable level many orders of magnitude lower called the *viral set point.* It is known that higher set points of viral load and lower T-cell counts are loosely predictive of shorter periods of clinical latency. Eventually, a prolonged period of homeostasis between the virus and the immune system collapses, and AIDS ensues.

Chronic Immune Activation and Progression to AIDS

After the acute stage, HIV infection induces a high degree of proliferation and turnover of CD4 and CD8 T cells. The massive immune activation can be explained by the circulation of many soluble factors, including TLR ligands. HIV infection appears to activate plasmacytoid DCs by stimulation of TLR7 to secrete interferon-α (IFN-) and proinflammatory cytokines, using both TLR8 and DC-SIGN to infect these cells.[14] In turn, stimulated DCs activate T cells, which are also being directly activated through TLR ligands. Bacterial products from the mucosa (*e.g.*, LPS) and HIV protein products, such as Nef, Env, Vif, and so on, are mediators of this immune activation. Other microbial infections (viral, bacterial, or fungal) can stimulate the different TLRs and result in CD4 and CD8 T-cell activation and apoptosis. This rampant immune activation is thought to lead to the eventual collapse of the immune system.

Anti-HIV Cellular Immunity

In individuals with HIV infection, the initial control of viremia occurs with the initial expansion of HIV-specific CD8 T cells. The importance of anti-HIV cytotoxic T cells is suggested by the development of viral escape mutations that are driven by immune selection pressure and evade the immunological response. In addition to their cytotoxicity, CD8 T cells secrete chemokines, such as RANTES and MIP-1β, which inhibit viral entry via CCR5, and IFN-γ, which activates immune cells and increases HLA expression (Chapter 10). Although severely reduced in number, IFN-γ–secreting HIV-specific CD4 T cells are present in individuals with HIV infection. The role of adaptive cellular immunity in protection against natural infection is currently challenged, since about 40–60% of noninfected but exposed individuals do not present with detectable anti-HIV responses.

Mechanisms of T-Cell Depletion

Three major mechanisms of T-cell depletion have been reported: direct lytic infection, apoptosis, and autophagy. Direct lytic infection is the result of massive activation of the immune system with production of inflammatory cytokines, as in the GALT (see Cytokines in HIV infection).

Apoptosis

Increased apoptosis of T cells in HIV infection was described early in the history of the epidemic. Several explanations have been offered: *(i)* HIV-induced apoptosis of infected cells (viral cytopathic effect); *(ii)* bystander effect from HIV-infected neighbor cells releasing viral proteins; *(iii)* death of HIV-specific effectors following their migration to infected sites; *(iv)* perturbation of proapoptotic signaling molecules on immune cells secondary to the chronic immune activation; and *(v)* destruction of HIV-infected cells by immune effectors.

Late HIV infection is associated with the dominance of a syncytia-inducing form of the virus. Syncytia formation (clustering of CD4 T cells and membrane fusion) occurs through the interaction of HIV Env and CD4/CXCR4 on neighboring cells. These cells are more prone to undergoing apoptosis through a Fas-dependent pathway.[15] Most of the HIV proteins have been implicated at one time or another in HIV-induced apoptosis.

Autophagy

Autophagy is a process by which cytoplasm and organelles are sequestered and directed toward lysosomal pathways and histone deacetylase.[16] This process has been implicated in both the prevention and induction of apoptosis, reflecting common regulatory factors shared by both (*e.g.,* tumor necrosis factor [TNF]–related apoptosis inducing ligand [TRAIL], FADD, DAPk, ceramide, and Bcl-2). HIV Env has been shown to be a stimulus for autophagy in uninfected CD4 T cells via its interaction with CXCR4. Inhibition of the autophagic pathway prevents Env-induced cell death in uninfected cells *in vitro,* demonstrating that this mechanism contributes to the loss of uninfected cells.

Anti-HIV Humoral Immunity

After establishment of HIV infection, neutralizing antibodies are produced; however, the virus quickly mutates to avoid them, such that the host continues to respond to evolving viral mutants. The fact that antibodies can be effective in protecting hosts from HIV infection has been demonstrated in macaques and in a humanized mouse model of HIV infection.

INNATE IMMUNITY

Innate immunity mechanisms are characterized by their lack of antigen specificity and include epithelial barriers, the complement system, phagocytes, and antigen-presenting cells (APCs). Their role in HIV pathogenesis is complex, as their function is of most importance during acute infection but their contribution to immune activation may be deleterious in the chronic stage. Studies including individuals who were exposed to HIV but did not develop infection have suggested that an increased innate immune response generated in the mucosal microenvironment may explain the failure to develop a specific anti-HIV response.[17]

NK Cells in HIV Infection

NK cells are dramatically altered in HIV infection.[18] A small subset of NK cells has been found to express both CD4 and CCR5 or CXCR4. These NK cells can be infected by HIV and may serve as one of the sites of latent infection or can be activated and contribute to the state of immune chronic activation. CCR5 and inhibitory receptor expression are higher on NK cells in patients with HIV infection than in HIV-seronegative subjects. In contrast, there is reduced expression of surface receptors on NK cells that induce cytotoxic activity, such as NK-cell protein 30 (NKp30), NKp44, and NKp46. Antibody-dependent cellular cytotoxicity (ADCC) is reduced in patients with HIV infection, as well as the NK-cell responsiveness to IL-2. The expression of HLA-C–specific inhibitory NK-cell receptors has been found to be increased in patients with HIV. Interestingly, studies of Vietnamese patients who were exposed to HIV through IDU but were seronegative showed that the NK cells of these patients not only secreted greater quantities of chemokines compared with those of the controls but they also had greater direct cytotoxicity. Genetic studies have suggested that inheritance of particular killer inhibitor receptor (KIR) alleles with their HLA ligands delays disease progression.[19] The two subsets of DCs, myeloid and plasmacytoid, play an additional role in HIV infection by stimulating innate immune responses, such as the type 1 IFNs, against HIV via plasmacytoid DCs. DCs may have opposing roles, with myeloid DCs acting as reservoirs and favoring HIV dissemination and plasmacytoid DCs inhibiting HIV replication by cytokine secretion. In fact, low levels of plasmacytoid DCs correlate with high viral loads, low CD4 T-cell counts, opportunistic infections, and disease progression.

Cytokines in HIV Infection

The dysregulation of the immune system produced by HIV infection includes significant perturbation in the balance of Th1 and Th2 cytokine levels. The Th1 cytokines IL-2, TNF-α, IFN-γ, and IL-12 decrease during HIV infection, whereas the Th2 cytokines, IL-10, and IL-4 increase or remain normal; levels of proinflammatory cytokines, such as IL-1, IL-6, and IL-8, also increase. Viral replication in HIV-infected T cells and monocytes is induced by IL-2, IL-7, and IL-15, as well as by the proinflammatory cytokines. These cytokines appear to induce viral replication by activating the host cell, a requirement for HIV productive replication. Some cytokines, such as IL-10, decrease HIV production, likely by inhibiting the synthesis of the activating cytokines and by decreasing the expression of CCR5 and other chemokine receptors. In addition, the HIV long terminal repeat (LTR) promoter contains sequences that bind cellular factors that are activated as a response to cytokine binding, such as nuclear factor (NF)-κB and AP1. IFN-α and IFN-β have activity against HIV, although their role of these cytokines *in vivo* is not well established and may have only an adjuvant effect.[20] Their activity might favor HIV infection, as shown by the upregulation of CCR5 by IFN-α, which can facilitate viral entry. Chemokines inhibit HIV infection by competing for viral binding sites. The α chemokine stromal cell–derived factor 1 (SDF-1) competes with lymphotropic HIV strains for binding to CXCR4, whereas the β chemokines macrophage inflammatory protein 1-α (MIP1-α), MIP1-β, and RANTES compete with macrophage-tropic strains for binding to CCR5.

CLINICAL FEATURES

If the HIV infection is left untreated, its natural history involves the progression through four clinical phases: acute retroviral syndrome, asymptomatic or latent infection, symptomatic HIV infection, and finally AIDS. Each clinical phase correlates with specific events in the interaction between HIV and the host immune system. A small percentage of patients become long-term nonprogressors, and an even smaller percentage become elite controllers (see Long-term nonprogressors/elite controllers).

Acute HIV Infection

Soon after infection, unopposed by effective host immune responses, HIV rapidly replicates and disseminates to lymphoid tissues (see Immunopathogenesis: gastrointestinal system) and to the systemic circulation, with viremia reaching as high as 10 million copies per milliliter. Plasma viremia typically peaks in 3–4 weeks after transmission, and then, as a result of the depletion of susceptible CD4 T cells and HIV-specific immune responses, the virus load precipitously declines, followed by more gradual decline for several weeks before reaching the set point.

Clinically, the acute phase of HIV infection is manifested by a flu-like illness, referred to as *acute retroviral syndrome.*[21] Two to 4 weeks after transmission, coinciding with the period of high plasma viremia and dissemination of virus to lymphoid organs, the majority of infected individuals experience a nonspecific infectious mononucleosis–like illness that lasts from a few days to several weeks. As the host develops HIV-specific immunity, the virus load decreases, CD4 and CD8 T cells recover, and the symptoms of the acute infection resolve. Although up to 90% of patients seek medical care for this illness, the nonspecific nature of the symptoms makes diagnosis of acute infection difficult, and most newly infected individuals are not diagnosed until much later. The public health implications of the acute HIV infection are enormous because the risk of transmission from individuals with acute infection appears to be much higher than that from those with established infection, in part because of the high viral load in the former.

Asymptomatic HIV Infection

The acute infection is followed by a prolonged asymptomatic or latent period that may last 8–10 years in adults but is much shorter in children. During this time, the HIV viral load fluctuates around a relatively stable set point.[22] The viral set point is a major determinant of infectivity and risk of disease progression, with higher viral loads being associated with more likely viral transmission, more rapid disease progression, and greater risk of death. The host immune response is insufficient to eradicate the infection but is enough to contain viral replication for many years. Although commonly thought to represent a stalemate between viral replication and CD4 T-cell production, this period is actually characterized by a steady and inexorable decline of CD4 T cells (50–75 cells per year).

CLINICAL PEARLS

Acute Infection Is an Opportunity for Early Human Immunodeficiency Virus (HIV) Diagnosis

- Acute HIV infection is a nonspecific viral syndrome, often described as being similar to infectious mononucleosis.
- Many patients present to a clinician at this stage, but most are not recognized as HIV infection.
- Irreparable damage to the host immune system occurs during this stage of HIV infection resulting in chronic immune activation and the eventual collapse of the immune system.
- HIV viral latency is established during the acute infection as HIV DNA integrates with the host genome resulting. Integrated viral genetic material makes cure of HIV impossible even after prolonged viral suppression with antiretroviral therapy (ART).
- ART initiated during the acute infection can halt the destruction of the body's memory T cells in the gut-associated lymphoid tissue (GALT) and lead to better long-term outcomes for the patient.
- The practical importance of early therapy of acute infection remains in question because patients who are able to achieve and maintain undetectable viral loads on ART do well despite having commenced treatment long after their acute infection.

Symptomatic HIV Infection (pre-AIDS)

As the infection progresses, most individuals develop clinical symptoms. The ability of the immune system to contain viral replication is overcome, and the viral load begins to increase. There is usually an inflection point in the CD4 T-cell curve marking the start of a period of more rapid decline in CD4 T-cell counts. As these counts fall, immunodeficiency, symptomatic disease, and AIDS eventually occur (Fig. 39.4).

End-Stage HIV Infection: AIDS

As the CD4 T-cell count drops to <200 cells/μL, the immune system's ability to fight infection is compromised to the extent

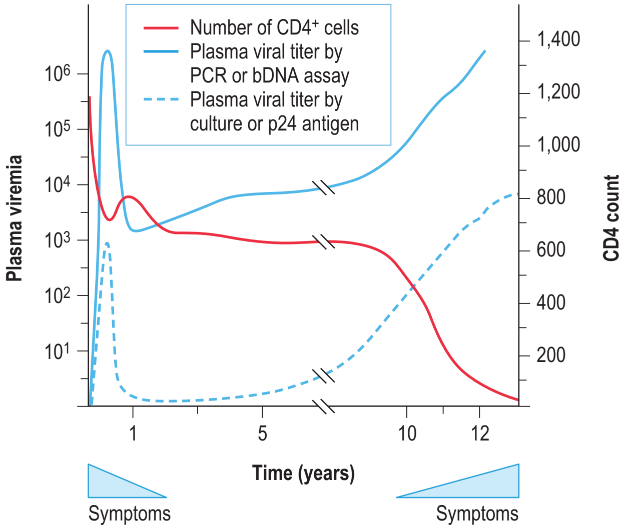

FIG 39.4 Natural course of human immunodeficiency virus (HIV) infection. The relationship between CD4 T-cell counts and viral loads over the course of infection in the absence of treatment. TABLE 39.1 **Opportunistic Infection Prophylaxis and Treatment in Adolescents and Adults***

Risk Factor	Agent	Prophylactic Medication
CD4 cell count <200 cells/μL	*Pneumocystis jiroveci*	Trimethoprim–sulfamethoxazole (TMP-SMX) or dapsone plus or minus pyrimethamine and leucovorin or aerosolized pentamidine or atovaquone
	Coccidioidomycosis	In endemic areas: fluconazole or itraconazole
CD4 T-cell count <100 cells/μL	*Toxoplasma gondii*	TMP-SMX or dapsone plus pyrimethamine plus leucovorin or atovaquone plus pyrimethamine plus leucovorin
	Histoplasmosis	In endemic areas: itraconazole
CD4 T-cell count <50 cells/μL	*Mycobacterium avium* complex (MAC)	Macrolide (clarithromycin or azithromycin) or rifabutin
	Cryptococcosis	In endemic areas: fluconazole or itraconazole
Purified protein derivative (PPD) >5 mm induration or recent tuberculosis (TB) contact but no active TB and no history of treatment for active or latent TB	*Mycobacterium tuberculosis*	Isoniazid (INH) + pyridoxine for 9 months; if unlikely to complete 9 month course and on highly active antiretroviral therapy (HAART): rifabutin plus pyrazinamide for 2 months
Contact with chickenpox or shingles in varicella-zoster seronegative individuals	Varicella-zoster	Varicella-zoster immunoglobulins (VZIGs)
Human immunodeficiency virus (HIV)–infected	*Streptococcus pneumoniae*	Pneumovax
	Meningococcus—for youth attending the military or college and consider for unvaccinated adults	Menactra
Negative anti-hepatitis B core antibodies (HBc) and previously unimmunized or underimmunized to hepatitis B	Hepatitis B	Recombivax-HB or Energerix-B
Negative anti-hepatitis A serology	Hepatitis A	Havrix

*For additional information see the current US guidelines at http://AIDSinfo.nih.gov.

that AIDS-defining illnesses begin to appear. On the basis of the CD4 T-cell count, prophylaxis for opportunistic infections is administered (Table 39.1). Without treatment, most patients will succumb to opportunistic infections within 2 years of developing AIDS.

Long-Term Nonprogressors/Elite Controllers

Some HIV-infected patients are called *long-term nonprogressors* (LTNPs) because they do not progress to AIDS after a defined period. One explanation for this phenomenon is the deletion of 32 nucleotides in the *CCR5* gene (*CCR5-δ32)*. This deletion, postulated to have originated from selective pressure exerted by the bubonic plague, is found in people of European Caucasian ancestry. The deletion renders the CCR5 receptor nonfunctional and offers protection against viral infection. Other mutations have been identified, such as the *CCR2-64I* mutation, the *SDF1-3'A* mutation, and the *RANTES-28 G* mutation; however, these mutations are found in only a minority of LTNPs.

Elevated levels of messenger RNA (mRNA) for the ARV cytidine deaminase APOBEC3G have been found in LTNPs compared with noninfected controls and most patients with HIV infection. An explanation for the finding of APOBEC3G in LTNPs is that these individuals are infected with a defective or less fit virus. More conventional mechanisms have been proposed for LTNPs, such as strong and broadly neutralizing antibody and/or cytotoxic T-cell responses. HLA-B27 and HLA-B57 have also been correlated with LTNPs. In children, CD8 HLA-DR$^+$ T-cell percentages of <5% at 1–2 months of age have been implicated in predicting LTNPs, presumably as a result of decreased T-cell activation and inflammation. In a subset of LTNPs, circulating autoantibodies to a conformational epitope in the extramembrane loop of CCR5 that induce downregulation of the coreceptor have been found. Interestingly, if the levels of those antibodies waned, the LTNPs would be more likely to progress to symptomatic disease.

TABLE 39.2 **Factors Affecting Human Immunodeficiency Virus (HIV) Disease Progression**

Inoculum size	Higher the inoculum the faster the disease progression
Age	Infected infants have a higher risk of rapidly developing acquired immunodeficiency syndrome (AIDS) at any given CD4 percentage Less common in adults
Viral set point	The higher the viral set point the faster the disease progression
Broad and robust cellular and humoral immune responses	These correlate with lower set points, but what parts of these and which one is more important are unknown
Coreceptor mutations: δ32 CCR5, CCR2-64 I, SDF 1-3' A	Homozygotes for the δ32 CCR5 mutation fail to develop disease; heterozygotes have a much longer period of clinical latency
T-helper 1 (Th1) responses: interleukin-2 (IL-2) and interferon (IFN)-γ levels	Found in subsets of long-term nonprogressors (LTNPs)
Autoantibodies to CCR5 HLA-B27, -B57, -DLR	Found in subsets of LTNPs to also correlate with Autoantibodies
APOBEC3G levels	Higher levels are associated with slower progression
Viral fitness	Less fit viruses are associated with slower disease progression

A rare group of HIV-infected individuals are able to control the viral load at very low levels without ART. These elite controllers display high expression of the T-bet transcription factor perforin, and granzyme B.[22] Table 39.2 summarizes factors that can affect HIV progression.

DIAGNOSIS AND MONITORING OF HIV INFECTION

Diagnostic Tests

The diagnosis of HIV infection depends on the detection of biological markers, produced either by the virus or by the infected host, which appear in a chronology that is typically consistent among individuals. The earliest virological markers, HIV RNA and HIV p24, can be measured 9–12 days and 14–19 days after infection, respectively. The period between infection and detection of HIV RNA is called the "eclipse period" (Fig. 39.5).

Enzyme Immunoassays

Various generations of screening enzyme immunoassays (EIAs) are able to detect anti-HIV antibody 2–6 weeks after HIV RNA is detected. Traditionally, the period between infection and detection of HIV antibody by a particular test is referred to as the "window period" for that assay. The window period for new generation combination EIAs has been shortened to about 2 weeks because in addition to detecting antibody to both HIV-1 and HIV-2, they also detect p24 antigen.[23]

Rapid HIV EIA Tests

Rapid enzyme immunoassays are the most commonly used HIV screening tests. Rapid HIV tests are self-contained EIAs that detect HIV in whole blood or oral fluid specimens and can be used at the point of care, yielding results within 30 minutes. Because results of rapid tests are available quickly, individuals can learn of their results in a single appointment.

For both EIAs and rapid tests, a negative result is conclusive and generally requires no follow-up testing. A common exception is that in individuals with possible recent exposure, antibody tests may be negative in the window period before seroconversion, so testing should be repeated within 1–2 months. A reactive EIA or rapid test requires further testing to confirm the diagnosis (Fig. 39.6). The Western blot assay identifies specific HIV antigens to which IgG antibodies in the patient's serum react and historically has been used to confirm positive screening tests results. However, because Western blots do not become diagnostically reactive until approximately 5–6 weeks after infection, nucleic acid amplification tests are now commonly used to confirm infection because they detect HIV infection well before the Western blot can show positive results. The current laboratory HIV testing algorithm as recommended by the CDC for serum or plasma specimens is shown in Fig. 39.6.

Nucleic Acid Amplification Tests

Nucleic acid amplification tests are used to detect HIV RNA or DNA in biological samples to diagnose and/or monitor HIV

infection. HIV RNA polymerase chain reaction (PCR; Chapter 96) is used to quantify the virus load or the extracellular viral RNA in plasma and is also measured by using qualitative assays. HIV RNA detection plays a valuable role in identifying early infection before seroconversion and in confirming reactive screening tests. Quantification of HIV RNA is also used to monitor the effectiveness of ART in suppressing viral replication. HIV DNA PCR is a qualitative assay used to detect HIV viral DNA in peripheral blood mononuclear cells. Detecting HIV DNA has allowed the early diagnosis of HIV in perinatally exposed infants and is still used for this purpose in international settings. HIV DNA PCR is not typically available for diagnostics in the United States, although more and more physicians are ordering this test.

Monitoring Tests

Once infection is confirmed, specific laboratory tests are performed at baseline and then periodically to monitor disease status and progression, to inform treatment decisions, and to identify end-organ toxicity. The CD4 T-cell count is used to assess immune function and is the most important factor in the discussion of short-term prognosis and determining whether prophylactic medications for opportunistic infections are needed. Once a patient is on ART, an increasing CD4 T-cell count also helps confirm the efficacy of the therapy.[24] In children younger than 5 years of age, CD4 percentage is preferred because it typically remains stable in the setting of age-related changes in absolute CD4 count in this age group.[25]

HIV Viral Load

Particularly for patients on ART, plasma HIV RNA (viral load) is the most important indicator of response to therapy. Optimal viral suppression is generally defined as a viral load persistently below the level of detection (<20–75 copies/mL, depending on the assay used) and is usually achieved in 12–24 weeks of effective ART.[24] Failure to achieve maximal viral suppression or detectable virus after a period of maximal suppression may indicate virological failure attributable to drug resistance.

KEY CONCEPTS

Other Human Immunodeficiency Virus (HIV) Tests

- *Genotyping:* helps to guide the choice of antiretroviral medications in patients with resistant virus by sequencing the viral genetic code and identifying mutations that confer resistance to specific agents or classes of agents.
- *Phenotyping:* similar information to genotyping but not widely used; based on growing engineered viruses with a patient's virus' genes in the presence of antiretrovirals to determine their resistance.
- *Viral fitness:* this least utilized assay is based on the phenotype assay except that it grows the virus without antiretrovirals to measure its intrinsic replicative capacity relative to a defined wild-type virus.

All three of these assays present data as if there is only one virus strain in the body; in reality, there are numerous viral strains at any one time, with many more archived in cells; these assays detect the dominant strain in the circulation, neglecting the other strains, which may account for up to 20% of the circulating viral particles. Given this limitation, when genotyping results are utilized for changing therapy, old treatment regimens and previous genotype results must be taken into consideration.

Drug Resistance: HIV Genotype Versus Phenotype

Viral resistance to ARV agents can be assessed by either HIV genotype or phenotype assays. Genotype assays, based on PCR and genomic sequencing, identify the presence of key mutations that confer anti-HIV drug resistance. Phenotype assays assess the ability of HIV to replicate *in vitro* in the presence of ARV agents. The assay is performed by isolating certain key regulatory genes from HIV, usually protease and reverse transcriptase, inserting them into standardized viral constructs containing an indicator cassette, and infecting cell lines in the presence of ARV agents. The results are compared against control viral isolates and expressed as a fold-change in viral susceptibility. Phenotyping assays remain very expensive, and large studies have failed to conclusively prove a clinical advantage of phenotype assays over genotype assays. The phenotype assay quantifies susceptibility and is typically used by experts evaluating individuals who have accumulated resistance and failed multiple regimens.

Testing for Viral Tropism and Abacavir Hypersensitivity

Additional assays should be performed before the initiation of specific ARV medications. A viral tropism assay should be performed before initiation of a CCR5 antagonist. HLA-B*57:01 testing is indicated before initiation of abacavir, as this HLA phenotype is associated with abacavir hypersensitivity in 5–8% of patients early in the course of treatment.

TREATMENT

Antiretroviral Therapy: Attacking HIV's Lifecycle

Combinations of ARV medications are used to maximally inhibit HIV replication and to reduce HIV-associated morbidity and mortality. Combination ART refers specifically to a combination of at least three ARV medications inhibiting the HIV lifecycle (see Fig. 39.3; Fig. 39.7). Current US guidelines recommend initiation of ART-naïve persons with a combination of two nucleoside reverse transcriptase inhibitors (NRTIs) plus an integrase strand transfer inhibitor, a nonnucleoside reverse transcriptase inhibitor (NNRTI), or a protease inhibitor (PI) with a pharmacokinetic enhancer (cobicistat or ritonavir). In ART-experienced patients, modification of ARV regimens and use of other classes of ARVs is guided, in part, by consideration of a number of factors, including viral resistance patterns, potential side effects, available medication formulations, pill burden, frequency of dosing, tolerability, short-term and long-term adverse event profiles, desire for pregnancy, and desire to preserve subsequent treatment options.[24,25]

When to Start Therapy

There are significant data to support treating all HIV-infected individuals with ART and starting treatment as soon as possible after diagnosis to reduce morbidity and mortality and to prevent transmission of HIV (see also HIV prevention). Randomized controlled trials have demonstrated that ART should be initiated in all patients with HIV infection, regardless of disease stage. The urgency to initiate ART is greatest for patients with lower CD4 counts, in whom the absolute risk of opportunistic infections, non-AIDS morbidity, and death is highest. However, the START (Strategic Timing of Anti-Retroviral Therapy) and the French National Agency for Research on AIDS and viral hepatitis (ANRS) 12136 "Temprano" trials provide the evidence that morbidity and mortality is reduced in individuals with CD4 counts >500 cells/mm^3 at the start of ART, resulting in strong recommendations, from both the US HIV treatment panel and the World Health Organization (WHO), to initiate ART in all patients regardless of CD4 cell count. In the START trial—a large, multinational, randomized controlled clinical trial with 4685 participants—ART-naive adults with CD4 counts >500 cells/mm^3 were randomized to initiate ART soon after randomization or to wait to initiate ART until their CD4 counts declined to <350 cells/mm^3, or until they developed a clinical indication for therapy. Serious AIDS or non-AIDS events endpoint was reported in 42 (1.8%) early ART participants and in 96 (4.1%) deferred ART participants (hazard ratio [HR] 0.43, favoring early ART [95% confidence interval (CI), 0.30–0.62; p < 0.001]). The majority (59%) of clinical events in the delayed ART arm occurred in participants whose CD4 counts were still >500 cells/mm^3, evidence for a benefit of immediate ART even before CD4 count declines below this threshold. The TEMPRANO ANRS 12136 study—a study of more than 2000 participants in Cote d'Ivoire, who were randomized to immediate or deferred ART—showed the benefit of immediate treatment over deferred treatment in reducing a combination of all-cause deaths, AIDS diseases, non-AIDS malignancies, and non-AIDS invasive bacterial diseases,

even among participants who had baseline CD4 counts >500 cells/mm^3. Earlier ART initiation appears to increase the probability of restoring normal CD4 counts, a normal CD4/CD8 ratio, and lower levels of immune activation and inflammation, as summarized in the US adult treatment guidelines.[24] Individuals initiating ART during the first 6 months after infection also appear to achieve lower immune activation levels and better immune function during ART-mediated viral suppression compared with those who delay therapy.[25]

Recommendations for initiating therapy in children have always been relatively more aggressive compared with those for adolescents and adults because most infected children were infected perinatally and experience rapid disease progression.[26] The decision to initiate ART should always include consideration of a patient's comorbid conditions, willingness, and readiness to initiate therapy. ART may be deferred because of clinical or psychosocial factors, with the goal of initiating therapy as soon as possible once barriers to successful treatment have been reduced.

Antiretroviral Agents

There are more than 20 approved ARV drugs that are classified into six classes based on their chemical structure or the viral lifecycle step that they inhibit (see Fig. 39.7). The classes of ARV agents currently available include NRTIs, NNRTIs, PIs, fusion inhibitors, integrase inhibitors, and CCR5 antagonists.

Reverse Transcriptase Inhibitors, Protease Inhibitors, and Integrase Inhibitors

Modified versions of cellular nucleosides, NRTIs, once triphosphorylated *in vivo,* are incorporated into the proviral DNA by HIV reverse transcriptase (RT) and induce premature chain termination, thereby inhibiting successful conversion of the viral RNA to DNA. NNRTIs bind to RT and induce a conformational change such that RT is unable to bind with nucleotides. PIs act on viral protease, preventing the cleaving of the posttranslational viral polyproteins necessary for the maturation and infectivity of viral particles. Integrase inhibitors prevent strand transfer of viral DNA and thus block the incorporation of the completed HIV DNA copy into the host-cell DNA.

Fusion Inhibitors, CCR5 Blockers, and Low-Molecular-Weight Inhibitors

Fusion inhibitors and CCR5 antagonists inhibit HIV entry into host cells. Fusion inhibitors bind to viral gp41 and block the conformational changes necessary to induce fusion of the viral particle with the host cell. CCR5 antagonists bind to the CCR5 chemokine coreceptor on host cells, inducing a conformational change that impedes CCR5 interaction with HIV gp120, thereby preventing HIV entry into host cells.

Low-molecular-weight inhibitors of HIV binding to the CD4 molecule are a new approach. Epigallocatechin gallate, by blocking gp120 binding to the CD4 molecule, has been shown to inhibit the infections of CD4 T cells in culture by wild-type viruses, setting the stage for a phase I/II study in humans (Fig. 39.8).[27]

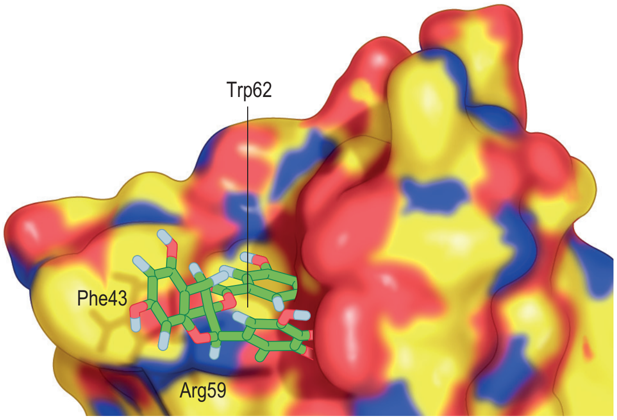

FIG 39.8 Epigallocatechin gallate (EGCG) binding to CD4. Recent studies indicate that polyphenolic EGCG, a component of green tea, can bind to the human immunodeficiency virus (HIV) binding site of CD4 (KD = 10 nM, as measured by nuclear magnetic spectroscopy) and potentially interfere in viral infection by interaction with three key amino acids in the D1 domain of the CD4 molecule (tryptophan 62, phenylalanine 43, and arginine 59). (From Williamson MP, et al. Epigallocatechin gallate, the main polyphenol in green tea, binds to the T-cell receptor, CD4. J Allergy Clin Immunol 2006; 118: 1369–74.)

IMMUNORECONSTITUTION AFTER THERAPY

Return of T Cells: Memory T Cells, Then Naïve T Cells

To varying degrees, the immune system is able to recover following initiation of therapy, a process called *immunoreconstitution.*[28] Upon start of ART in patients who are compliant and able to tolerate the regimen, the initial CD4 T-cell count is the best predictor of a successful outcome. Rapid reduction in the viral load, often to an undetectable level, is one of the earliest changes following initiation of ART, reflecting the ability of combination ART to rapidly suppress viral replication. Lagging behind the drop in viral load is the rise in CD4 T-cell values. An initial increase in circulating cells occurs in 3–6 months as a result of a decrease in immune activation and subsequent migration of memory T cells (CD4$^+$, CD45RO$^+$) out of the lymphoid compartment. A more gradual rise in total CD4 T cells occurs over the course of 3–5 years with the appearance of new naïve (CD4$^+$, CD45RA$^+$, CD62L$^+$) and memory T cells. Interestingly, a substantial minority of patients never reach a normal level of CD4 T cells but, instead, reach a plateau at lower levels. Primary drug prophylaxis and some secondary drug prophylaxis for opportunistic infections may be discontinued in patients once the CD4 T-cell count reaches >200 cells/mm^3 and is maintained for more than 3–6 months. Cellular and humoral responses to most pathogens also recover with rising CD4 T-cell counts. Of interest, a low CD4 T-cell count at the time of initiating therapy predicts a poor response to bacterial vaccines even after recovery of CD4 T-cell levels, suggesting a lag in the return of naïve CD4 T cells.

CLINICAL PEARLS

Immunoreconstitution Inflammatory Syndrome (IRIS)

- IRIS is typically found 2–3 weeks after initiating antiretroviral therapy (ART).
- Patients often become profoundly ill and require hospitalization.
- Steroids are sometimes useful in the treatment.
- Clinicians may prevent IRIS by initiating ART only after treating opportunistic infections.

Immune Reconstitution Inflammatory Syndrome

Immune reconstitution inflammatory syndrome (IRIS) is a well-known, if incompletely understood, response in patients with AIDS after initiating ART.[29] IRIS is characterized by an acute paradoxical worsening of inflammatory symptoms of treated opportunistic infections or the unmasking of previously subclinical, untreated infections related to the recovery of immune responses to opportunistic pathogens. IRIS occurs within weeks of ART initiation as the memory and effector antigen-activated CD4 T-cell population recovers. A recent systematic review found that IRIS developed in 13% of patients after initiation of ART.[28] The most predictive risk factor for the development of IRIS was a low CD4 T-cell count at the start of ART, with the incidence of IRIS increasing exponentially as the CD4 T-cell count declined. IRIS develops more commonly in patients with cytomegalovirus (CMV) retinitis, cryptococcal meningitis, progressive multifocal leukoencephalopathy, and tuberculosis. Studies reported that as many as 4% of patients with IRIS died, but the proportion was much higher if the syndrome was associated with cryptococcal meningitis.[29]

Hyperallergenic State Associated With Immunoreconstitution

Another complication possibly associated to IRIS is the appearance of asthma in children who were perinatally infected with HIV and received combination ART since infancy.[30] This condition may be mediated by CD4 T-cell activation, release of Th2-type cytokines, and loss of Tregs and tolerance. In support of this concept, Gingo et al.[31] reported at least a 20% prevalence of asthma in adults with HIV infection compared with that of 8.8% in the general population. In a subsequent pediatric study in which pulmonary function testing was objectively measured by spirometry, the following findings emerged: Nonreversible obstructive pulmonary disease was present in youth who had been perinatally infected with HIV and possibly in those exposed to HIV but were uninfected. This pulmonary disorder contains elements of asthma and chronic obstructive pulmonary disease (COPD) and closely resembles the asthma–COPD overlap syndrome. Chronic infections and immune dysregulation appears to play a significant role in this complication of HIV infection.[32]

PREVENTION

Prevention of Mother-to-Child Transmission

More than 90% of children living with HIV worldwide were infected through mother-to-child transmission during pregnancy, around the time of birth, or through breastfeeding.[33] Efforts to prevent this transmission hold the most promise in reducing the number of children infected with HIV, and these efforts include *(i)* early identification of HIV infection in pregnant women through routine antenatal testing; *(ii)* provision of ARV medications to both the pregnant woman and her infant[34,35]; *(iii)* delivery by elective cesarean section, when indicated; *(iv)* complete avoidance of breastfeeding when safe and sustainable alternatives are available; *(v)* widespread availability of educational programs addressing HIV infection; *(vi)* prevention of HIV perinatal transmission; and *(vii)* HIV counseling and testing services.[35,36]

Prevention of Sexual Transmission

Several biomedical interventions have the potential for radically changing the patterns and rates of HIV transmission. These include male circumcision and expanded use of ART in infected individuals to prevent ongoing infection (treatment as prevention) or prophylactically in uninfected individuals either before or after potential exposure to HIV to prevent acquisition of infection (preexposure prophylaxis [PrEP] and postexposure prophylaxis).

Male Medical Circumcision

The penile foreskin contains HIV-susceptible cells and is a potential portal of viral entry. Randomized controlled trials in several African countries have indicated that male medical circumcision reduces the risk of heterosexually acquiring HIV infection by 50–60%.[37] The WHO recommends male circumcision as part of a comprehensive HIV prevention package; however, condom use and other prevention modalities remain important in HIV prevention. There was only a modest benefit for the female partners of the circumcised men. In fact, in some circumstances, the risk of transmission to women from men with HIV infection who have undergone circumcision may be increased, perhaps through exposure to infected blood attributed to resumption of sexual activity before the circumcision site has fully healed.[37]

Preexposure Prophylaxis

Recently, two different modalities of ART have been found to decrease acquisition of HIV when used by uninfected individuals before their exposure to the virus as PrEP: topically applied ARV medications and systemic ART. Topically applied ARVs have been shown to block the acquisition of HIV in women from their partners with HIV infection by 35–54%. The Centre for the AIDS Program of Research in South Africa (CAPRISA 004) trial was the first double-blind randomized controlled trial demonstrating the efficacy of vaginally inserted gel containing the ARV medication tenofovir disoproxil fumarate, compared with a placebo gel, in preventing HIV transmission from men with HIV infection to their uninfected partners. Vaginal PrEP represents a promising intervention for preventing heterosexual transmission of HIV to women. This method may be particularly effective because women are able to initiate and control its use to protect themselves from infection.

Prophylactic Antiretroviral Therapy

ARVs taken prophylactically have also been shown to be effective in reducing the transmission of HIV both in MSM and in heterosexual individuals and couples. The multinational Preexposure Prophylaxis Initiative trial demonstrated that daily oral combination therapy with emtricitabine and tenofovir disoproxil fumarate (FTC-TDF) reduced the incidence of HIV among MSM by 44% compared with placebo. Daily oral FTC-TDF was also shown to reduce HIV incidence among heterosexual individuals by 63–78% and by 73% among heterosexual discordant couples. Despite these successful trials, preliminary results of one PrEP trial have failed to show similar efficacy for preventing HIV acquisition among heterosexual women.

Expanded Treatment With Antiretroviral Therapy

The expanded use of ART in infected individuals has been shown to reduce HIV transmission to uninfected partners. Both "Treatment as Prevention" and "Test and Treat" strategies involve the use of ART in individuals who do not otherwise meet the criteria for ART initiation with the express purpose of reducing transmission to others. In both approaches, ART is initiated regardless of CD4 count or viral load to reduce the viral load in the genital secretions of infected partners and thereby reduce HIV transmission to uninfected partners. The efficacy of the "Treatment as Prevention" model is demonstrated in the multinational HIV Prevention Trials Network (HPTN 052) clinical trial that examined the effectiveness of ART to prevent the sexual transmission of HIV in serodiscordant couples. Serodiscordant couples (1763 in number) were randomly assigned to have the infected partner either start ART immediately upon enrollment or to defer ART until immunological or clinical criteria were met. Of 28 genetically linked infections that occurred during the trial, only 1 infection occurred in couples assigned to receive immediate treatment, representing a 96% reduction in the risk of HIV transmission. There were also fewer morbidity and mortality events in the early-treatment group, suggesting a therapeutic benefit from early treatment as well.

The fundamental paradigm for "Test and Treat" programs is the same as that for "Treatment as Prevention" programs. "Test and Treat," however, emphasizes the need for universal voluntary routine HIV testing and initiating ART immediately in those found to be positive regardless of CD4 count or viral load. Although the approach remains controversial, with concerns regarding drug resistance, increased sexual risk taking in treated individuals, and societal cost-effectiveness, this approach may, over time, prove to be an effective prevention modality.

HIV VACCINES: CLINICAL TRIALS

Preventive Vaccines

The production of an effective HIV vaccine has been thwarted by the extreme rate of mutation in the virion and the sequestration of the virus in impenetrable reservoirs, predominantly the nonreplicating CD4 T cell. More than 30 HIV vaccines have been tested in human trials, including those with recombinant env gp120 proteins with adjuvants, HIV DNA plasmids, viral vectors, and prime-boost designs.[38] These vaccines have, for the most part, yielded disappointing results. Phase III trials of VAX003 in Thailand (AIDSVAX B/E plus alum) and VAX004 in North America and Europe (AIDSVAX B/E plus alum) showed no protection against HIV infection. Naked HIV DNA with cytokines IL-15, IL-12, and chemokine receptor 005 with and without electroporation has not been effective. Pox virus HIV vaccines in the STEP trial of North and South Americas and the Phambili trial in South Africa (Ad5-HIV trivalent vaccine) were ineffective in stopping HIV entry or postinfection viremia. However, the phase III trial RV144 in Thailand (ALVAC-HIV vCP1521 + AIDSVAX gp120 B/E) showed possible protection against HIV infection in heterosexual men and women.[38]

In addition to the goal of developing an HIV vaccine that elicits neutralizing antibodies, the search for a vaccine that stimulates a protective CD8 cytotoxic T-cell response continues. Association of certain major histocompatibility complex (MHC) molecules with HIV disease progression is clearly linked to the cytotoxic T-cell responses. Unfortunately, the HIV vaccine-induced cytotoxic CD8 T-cell response is insufficient to halt the progression of acute or chronic HIV disease. This was clearly indicated in the STEP clinical trial, in which the CD8 T-cell effects were the same between HIV-infected vaccinees and sham HIV-infected vaccinee controls. Qualities of effector and central memory CD8 T cells that would be protective include *(i)* production of cytotoxic cytokines (*e.g.,* IFN-γ and IL-2); *(ii)* rapidly replicating capacity; *(iii)* cytotoxic potential; *(iv)* high affinity for HIV antigens; *(v)* inhibition of HIV replication; *(vi)* recognition of specific HIV epitopes restricted by protective HLA-B antigens; *(vii)* central memory cells with long life spans; and *(viii)* rapid-attack memory cells at mucosal HIV entry sites. A high-level collaboration of preeminent clinicians and scientists has proposed the modification of the partially successful RV144 vaccine with the goal of producing a new HIV vaccine that will broadly neutralize HIV and variants of HIV that emerge under selective pressure (Table 39.3 and Table 39.4).[39] These modifications include changes in the viral epitopes, vaccine adjuvants, and use of a different clade as the construct of the virus. The goal of this new proposal is to use the information of many previous HIV trials to produce an ideal HIV vaccine that will prevent the spread of HIV infection in children and adults.

Therapeutic Vaccines

A therapeutic vaccine is one in which the vaccine is used after infection occurs, aiming to induce antiviral immunity to alter the course of disease. This would be accomplished by controlling viremia or reducing the viral set point in infected patients. Primate models suggest that just such a result is possible, especially with cellular immunity–inducing vaccines. To date, however, data from human studies have not shown any conclusive benefit in using therapeutic vaccines alone. Using a therapeutic vaccine in combination with ART is another approach currently under investigation. A small study of a therapeutic vaccine in 25 individuals with HIV infection produced a 1 $\log_{10}$ reduction in viral load compared with placebo-treated individuals with HIV infection.[40] However, HIV disease progression was not seen with this therapeutic vaccine in limited follow-up, indicating the need for longer follow-up and larger clinical trials before any measure of success can be claimed.

Future for HIV Vaccines

The general pessimism that prevailed in the scientific community after the failure of the STEP vaccine trial is gradually being replaced by cautious optimism as a result of the limited success of the RV144 clinical trial in Thailand. In addition, there is general belief that more basic research exploring vaccine design and

TABLE 39.3 Post RV144 Vaccine Combinations

Improve Frequency, Magnitude, and Polyfunctionality of CD4$^+$ T-Cell Response to HIV-1 Envelope Products	Improve Clade-Specific Antibody Responses to gp120	Improve Durability of Antibody Response Through Adjuvants
ALVAC (ZM96) +/–DNA	Bivalent clade C recombinant gp120 protein (strains 1086 and TV-1) construct	Alum, MF59, AS01$_B$

trials in animals will lead to important clues for human study. Illustration of clinical trials in antiretroviral-treated macaques may be applied to humans in future by Byrareddy et al and Nishimura et al. Monoclonal antibody specific for CD4 T cell surface integrin ($\alpha4\beta7$) disrupts cellular trafficking of CD4 T cells with gastrointestinal tissue mucosal vascular addressin cell adhesion molecule (MAdCAM1). The CD4 T cell counts remained steady, CD8 T cell immunity sharply increased, and HIV replication became undetectable for up to 2 years.[41,42] As illustrated by these HIV vaccine studies in animals, understanding the immune correlates of vaccine efficacy is an absolute requirement for judging the success of an HIV vaccine.

ON THE HORIZON

- Production of newer antiretroviral drugs, including those used for postexposure prophylaxis with greater specificity for interrupting events in the viral lifecycle and with fewer side effects for patients.
- Investigation of new microbicidal drugs that can be safely applied before exposure for protection against human immunodeficiency virus (HIV) transfer.
- Development of preventive and therapeutic vaccines for HIV/acquired immunodeficiency syndrome (AIDS) that induce strong viral neutralizing antibody power and strong CD8 T-cell cytotoxic responses.
- Testing of gene construct-modified autologous hematopoietic stem cells capable of halting HIV replication.

TRANSLATIONAL RESEARCH NEEDS AND CONCLUSIONS

The quest for better ARV therapeutic agents continues, with the goal of greater selectivity and fewer side effects. However, the eradication of HIV/AIDS can only be approached practically with a preventive vaccine that elicits strong HIV-neutralizing ability and generates a strong cytotoxic CD8 T-cell response specific for HIV antigens. The approach to cure with gene therapy is perhaps the most sophisticated translational research venture. Using viral vectors to place gene constructs within nuclear DNA that prevent HIV replication is the goal of such research. Arguably, the most advanced form of this genetic engineering to halt HIV replication is the zinc finger endonuclease approach to disrupt specific genes necessary for the lifecycle of HIV. Adoptive transfer of autologous zinc finger–treated stem cells with infinite replication capacity may be an attractive future for individuals already infected with HIV.[43] The extraordinary experiment of HLA-matched and CCR5-δ35 deletion of hematopoietic stem cell immunoreconstitution of an patient with HIV infection ("Berlin Man") is a proof of concept of molecular and genetic engineering to cure HIV infection, a technique totally impractical to the millions of patients with HIV infection worldwide.[44] Nevertheless, this "one in a million" chance experiment has demonstrated the survival advantage of lymphocytes that cannot become infected with HIV.

HIV, a type 1 retrovirus, contains merely 9 genes, but those 9 genes have so far thwarted all scientific efforts toward finding a cure of its infection in humans. Optimism is warranted, however, because of the enormous knowledge base the study of HIV has generated in understanding the many arms of innate and adaptive immunity protecting humans and the promise of a curative treatment or vaccine for HIV. The HIV/AIDS pandemic has also brought the sobering realization that other new and potentially deadly pathogens may yet emerge to strike at humanity. Perhaps no other disease has caused so much to be learned so fast. In the developed world, HIV causes chronic infection, rather than certain death, thanks, in large part, to the use of ARV drugs. More novel drugs are in development as a result of the new-found understanding of the molecular biology of HIV. HIV continues to perplex and fascinate virologists and immunologists, and it continues to teach humility to clinicians.

MULTIPLE-CHOICE QUESTIONS

1. Globally the segment of the population with the highest human immunodeficiency virus (HIV) infection rate is that of the:
   A. Adult male
   B. Adult female
   C. Adolescent male
   D. Adolescent female

2. The rapid HIV diagnostic screening test (results in 30 minutes) most commonly used is:
   A. HIV RNA
   B. Enzyme immune assay
   C. HIV DNA
   D. Western blot

3. Worldwide, a cure for HIV/AIDS will most likely happen with which treatment?
   A. Therapeutic vaccines
   B. Combination antiretroviral therapy
   C. Preventive vaccines
   D. Male circumcision

4. The first lymphocyte subpopulation to return in the immunoreconstitution observed after antiretroviral treatment of immunosuppressed patients with HIV infection is:
   A. CD4 memory cells
   B. CD19 memory cells
   C. CD4 naïve T cell
   D. CD8 naïve T cell

Autoantibody-Mediated Phenocopies of Primary Immunodeficiency Diseases

Sarthak Gupta, Sarah K. Browne

Anticytokine autoantibodies have been identified in health and disease, with their role in pathogenesis ranging from none to directly causal. In fact, it is becoming increasingly recognized that neutralizing, high-titer autoantibodies cause a variety of potentially life-threatening illnesses. Their manifestations are diverse, and their clinical presentation is generally a reflection of the cytokine pathways that are rendered functionally deficient.

Examples include pulmonary alveolar proteinosis (PAP) caused by anti–granulocyte macrophage–colony-stimulating factor (GM-CSF) autoantibodies[1]; disseminated nontuberculous mycobacterial (NTM) and other opportunistic infections and anti–interferon-γ (IFN-γ) autoantibodies[2]; chronic mucocutaneous candidiasis (CMC) and anti–interleukin (IL)-17A, anti–IL-17F, or anti–IL-22 autoantibodies[3,4]; and staphylococcal skin infection and anti–IL-6 autoantibodies[5] (Table 40.1). In each of these cases a high-titer, biologically active autoantibody has been identified in association with a unique clinical syndrome. Although this list is not exhaustive, these diseases are of particular interest in that the clinical manifestations are often similar to those in patients with genetic defects in the same cytokine-associated pathways. The mendelian defects that confer a similar phenotype to their anticytokine autoantibody counterpart also provide a strong biological rationale for establishing the autoantibodies as causal. Although a number of other anticytokine–autoantibody associated syndromes such as pure red-cell aplasia (antierythropoietin autoantibodies)[6] and severe osteoporosis in celiac disease (antiosteoprotegerin autoantibodies)[7] have been described, this chapter focuses on those that increase susceptibility to infection.

KEY CONCEPTS

Anticytokine Autoantibody–Associated Primary Immunodeficiency Diseases

- Anticytokine autoantibodies have been identified in a group of patients with immunodeficiency diseases characterized by the development of high-titer, neutralizing autoantibodies to cytokines.
- The clinical manifestations in patients with anticytokine autoantibodies are similar to those seen in patients with genetic defects in the pathway of the target cytokine.
- Immunodeficiency syndromes described include those associated with anti– granulocyte macrophage–colony-stimulating factor (GM-CSF) autoantibodies and pulmonary alveolar proteinosis (PAP); anti–interferon (IFN)-γ autoantibodies and severe immunodeficiency; anti–interleukin (IL)-17A, anti–IL-17F, and anti–IL-22 autoantibodies and chronic mucocutaneous candidiasis (CMC); and anti–IL-6 autoantibodies and staphylococcal skin infection.
- Management of these syndromes involves treating the consequences of the autoantibody (*e.g.,* infectious manifestations, lung disease) or targeting the autoantibody itself.

There are numerous commonalities and distinctions worth highlighting among anticytokine autoantibody–associated immune deficiency. Shared in common is the presence of high-titer, neutralizing anticytokine autoantibodies of the immunoglobulin G (IgG) isotype. PAP caused by anti–GM-CSF autoantibodies appears to be primarily a lung disease largely resulting from disruption of GM-CSF–dependent pulmonary surfactant catabolism. *In vitro* studies using primary human cells and mouse work have demonstrated that anti–GM-CSF autoantibodies cause immune dysfunction, largely through transcription factor PU.1, which may explain pulmonary and extrapulmonary infections observed in PAP, particularly those opportunists known to be controlled by neutrophils or macrophages.[1] PAP caused by anti–GM-CSF autoantibodies is similar to severe immune deficiency caused by anti-IFN-γ autoantibodies in that both diseases have adult onset. On the basis of broad screening for other autoantibodies, it appears they make high-titer neutralizing autoantibody against only one cytokine and do not demonstrate an increased frequency of other autoantibodies or forms of autoimmunity.[1,2] Patients with autoantibodies against IL-17A, IL-17F, IL-22, and CMC are different in that, so far, all have had an underlying primary diagnosis of either autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APECED) or thymic neoplasia.[3,4] Thus in the case of APECED, a mendelian defect in the gene *AIRE,* which is responsible for negative selection for autoreactive T cells in the thymus, the onset of anticytokine autoantibodies and CMC occurs earlier in life. Occasionally, CMC is the initial presentation of thymoma (just as myasthenia gravis caused by antiacetylcholine receptor autoantibodies must prompt evaluation for thymoma) and highlights that for all anticytokine autoantibody–associated syndromes, the time line for development of anticytokine autoantibodies relative to the observation of clinical disease is largely unknown. Additionally, patients with thymoma and APECED can develop multiple anticytokine autoantibodies, although they have a proclivity for certain ones, including type I IFNs, IL-17A, IL-17F, IL-22, and, in the case of thymoma (but not APECED), IL-12. Given the presence of multiple neutralizing autoantibodies, and the role of the thymus in T-cell development that can lead to intrinsic T-cell defects that could also confer infection susceptibility, it is challenging to prove that a particular anticytokine autoantibody is the necessary and sufficient agent of disease pathogenesis. In the case of anti–IL-6 autoantibodies, high-titer, neutralizing anti–IL-6 IgG was demonstrated in one 11-month-old child with recurrent staphylococcal skin infections and low C-reactive protein-reactive protein (CRP), an IL-6–driven inflammatory marker.[5] The opportunity to identify common clinical features around this entity is limited, since other cases have yet to be identified.

TABLE 40.1 Anticytokine Autoantibody–Associated Syndromes and Their Phenotypically Similar Genetic Counterparts

Cytokine Target	Genetic Phenocopies	Clinical Manifestations	Laboratory and Radiological Manifestations	*In vitro* Evidence for Biological Activity	Infections	Comments
GM-CSF	GM-CSF receptor α or β subunits	PAP Insidious and progressive respiratory failure Newly described cases of isolated cryptococcal meningitis and *Nocardia* infection in individuals without human immunodeficiency virus (HIV) infection[17-19]	BAL fluid contains large foamy macrophages or monocyte-like macrophages and elevated levels of surfactant proteins Characteristic computed tomography (CT) of chest demonstrates ground-glass opacities with thickening of intralobular septae, "crazy paving." PFTs demonstrate restrictive and diffusion defects[1]	Anti–GM-cerebrospinal fluid autoantibodies inhibit pSTAT-5 production,[17] PU.1 expression , MIP-1α protein production	Pulmonary and extrapulmonary infections with *Nocardia, Aspergillus, Proteus, Histoplasmosis,* and *Cryptococcosis*[1]	Mutations in surfactant proteins have also been described SP-B, SP-C, or ABCA3, but are considered clinically distinct
IFN-γ^h	Mutations in IFN-γR1; IFN-γR2; STAT1; IL-12Rβ1; IL-12Rβ2; IL-12p40; NEMO; IRF8; ISG15	Chronic infections with intracellular pathogens, particularly lymphadenitis, skin, soft tissue, and bone infections; can be multiple organisms simultaneously or sequentially; reactive dermatoses; constitutional symptoms common	Elevated erythrocyte sedimentation rate, C-reactive protein-reactive protein (CRP), β_2 microglobulin, anemia, hypergammaglobulinemia. CT imaging may demonstrate abscess formation or osteomyelitis	Anti–IFN-γ autoantibodies inhibit pSTAT1 production(2, 11), IFN-γ inducible gene expression[29] and IL-12p70 and TNF-α protein production[2,11]	Nontuberculous mycobacteria, tuberculosis, nontyphoidal *Salmonella, Histoplasma, Penicillium, Cryptococcus, Burkholderia pseudomallei,* varicella-zoster virus[2]	Functional testing to evaluate downstream inhibitory effects of autoantibody important, (*i.e.,* plasma inhibition of IFN-γ–induced pSTAT1 production)
IL-17A IL-17F IL-22	IL-17RA IL-17F	Recurrent candidal infections of mucosal surfaces, nails, and skin Infection may become resistant to antifungals	None	Anti–IL-17 autoantibodies inhibit IL-17–induced IL-6[4]	*Candida* spp.	Reported only in the context of APECED and thymoma so far
IL-6	STAT3	Recurrent staphylococcal skin infections.	Undetectable CRP	Anti–IL-6 autoantibodies prevent IL-6–induced CRP mRNA[5]	*Staphylococcus aureus*	One case reported to date

GM-CSF, Granulocyte macrophage–colony stimulating factor; PAP, pulmonary alveolar proteinosis; BAL, bronchoalveolar lavage; PFT, pulmonary function test; pSTAT, phosphorylated signal transducer and activator of transcription test; MIP, macrophage inflammatory protein; SP, surfactant protein; ABC, adenosine triphosphate-binding cassette; IFN, interferon; NEMO, nuclear factor (NF)-κB essential modulator; IRF, interferon regulatory factor; TNF, tumor necrosis factor; APECED, autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia.

OVERVIEW OF PATHOPHYSIOLOGY

The pathophysiology of infection susceptibility is generally thought to result from a functional deficiency in the cytokine that is being neutralized (Chapter 9). It is believed that a high-titer autoantibody binds its respective cytokine target, thereby blocking downstream signaling and biological activity. For each anticytokine–autoantibody pair, it has been demonstrated that plasma or purified IgG from a patient with the anticytokine autoantibody prevents the activity of the targeted cytokine at the levels of signal transduction, gene transcription, and/or protein expression. In the case of anti–IFN-γ autoantibodies, it appears that antibody levels may track with disease activity[8]; however, for anti–GM-CSF autoantibodies, the results have been conflicting, and in neither case has the question been rigorously studied. It is also possible, but not yet proven, that antibody-binding avidity may influence the degree of disease severity as well. Thus it may be possible to have high-titer, lower avidity anticytokine autoantibodies leading to a similar disease phenotype to low-titer, high-avidity anticytokine autoantibodies.

The events that lead to the generation of anticytokine autoantibodies are poorly understood and are likely disease specific. Again, by comparing and contrasting these diseases, we may begin to understand some key factors. In the case of pulmonary alveolar proteinosis, it appears to be linked to tobacco use and also demonstrates a male predominance, which may be an artifact of the historically higher rates of smoking in men, particularly because no gender predilection has been observed among nonsmokers.[1] Although a large cohort of patients has been described in Japan, this disease is seen worldwide across all ethnicities and not within families, suggesting that if there is a genetic component, it is a complex one. No familial clustering has been identified in over 130 cases of anti–IFN-γ autoantibodies and opportunistic infection reported[2,9-12]; however, the disease is mostly seen in Asian-born Asians, suggesting that there may be an environmental trigger in the context of a common genetic background.

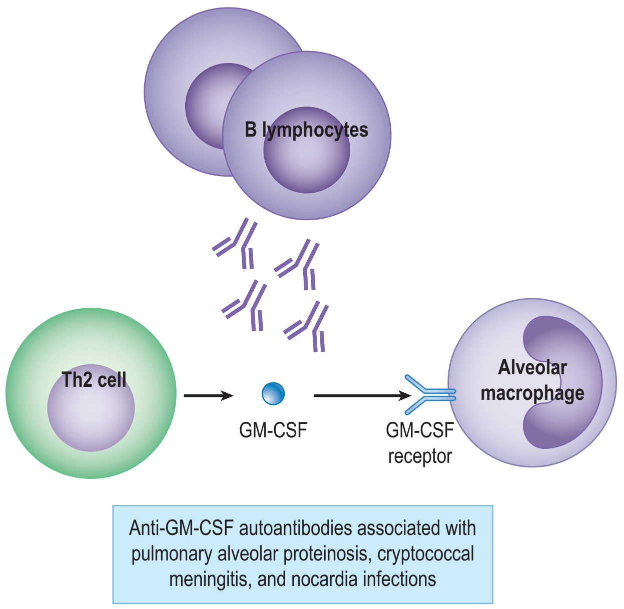
The fact that anticytokine autoantibodies are both IgG and high-affinity autoantibodies implicates the T-helper (Th) lymphocyte–dependent processes of class switching and affinity maturation. Interestingly, anti–IL-17A, –IL-17F, and –IL-22 autoantibodies appear directly linked to either the genetic AIRE deficiency of APECED or the acquired AIRE deficiency observed in patients with thymoma.[13] In both cases, thymic-driven disease appears to be leading to extensive B-lymphocyte dysregulation in the form of many autoantibodies, beyond just anticytokine autoantibodies. However, given that B cells may play a primary role in the development of autoimmunity in AIRE deficiency, the mechanisms underlying B-cell autoreactivity are likely complex.[13] Furthermore, evidence in rheumatological mouse models suggests that peripheral B-lymphocyte lineages leading to autoantibodies may fundamentally differ from those leading to development of protective antibodies.[14] Thus a common phenomenon of anticytokine–autoantibody production may, in fact, be a reflection of a convergence of multiple differing mechanisms.

ANTI–GM-CSF AUTOANTIBODIES AND PULMONARY ALVEOLAR PROTEINOSIS

GM-CSF is a hematopoietic stem cell (HSC) growth factor that binds the GM-CSF receptor, which is widely expressed on many cell lineages, including neutrophils, macrophage precursors, dendritic cells (DCs), erythrocyte progenitors, and megakaryocytes. The GM-CSF receptor is composed of two α and two β subunits, which together bind two GM-CSF molecules with high affinity and induce signal transduction and activator of transcription (STAT)–5 phosphorylation, nuclear translocation, and induction of master transcription factor PU.1. PAP was first described in 1958 by Rosen et al. as an idiopathic syndrome of respiratory failure, histopathologically characterized by alveolar filling with acellular periodic acid-Schiff–positive proteinaceous material.[1] The pathogenesis of PAP has since been linked to congenital or acquired defects in the GM-CSF signaling pathway.

The first clues to the etiological mechanism of PAP surfaced in 1994 and 1995 when a GM-CSF$^{-/-}$ and GM-CSF receptor β$^{-/-}$ mice, respectively, demonstrated pulmonary disease that was virtually identical to human PAP. Shortly thereafter, mechanisms involving disruption of GM-CSF signaling were linked to PAP in humans.[1] Primary PAP results from mutations in either the GM-CSF receptor subunits α or β and generally leads to severe respiratory failure and usually presents early in life. Autoimmune PAP results from neutralizing anti–GM-CSF autoantibodies, can also cause respiratory failure, and shares the same pulmonary histopathology as the primary form (Fig. 40.1). In contrast to primary PAP, the median age of diagnosis of the autoimmune form is 39 years, and its clinical course and severity is highly variable ranging from progressive respiratory decline to spontaneous resolution. A secondary form of PAP caused by qualitative or quantitative deficiency of alveolar macrophages, generally in the context of hematologic malignancies, iatrogenic immunosuppression, or inhaled toxins, has also been recognized.

Although the primary pathological process relates to impairment of GM-CSF–dependent catabolism of surfactant and its subsequent overaccumulation in pulmonary alveoli, there has



Anti-GM-CSF autoantibodies associated with pulmonary alveolar proteinosis, cryptococcal meningitis, and nocardia infections

FIG 40.1 Anti– Granulocyte Macrophage–Colony-Stimulating Factor (GM-CSF) Autoantibody Associated Pulmonary Alveolar Proteinosis (PAP). Autoimmune PAP results from impairment of GM-CSF–dependent catabolism of surfactant and its subsequent overaccumulation in pulmonary alveoli due to neutralizing anti–GM-CSF autoantibodies, leading to respiratory failure. Th2 cell, T-helper cell-2.

long been an association with opportunistic infections.[1] Beyond its role in pulmonary surfactant homeostasis, the GM-CSF receptor is widely expressed on immune cells, including neutrophils, monocytes, DCs, megakaryocytes, and erythrocyte progenitor cells, and influences cell differentiation, proliferation, and immune activation. GM-CSF has been shown in both humans and mice to facilitate not only terminal differentiation of monocytes to alveolar macrophages but also innate immune responses, primarily via induction of transcription factor PU.1. Cells isolated from bronchoalveolar lavage (BAL) fluid from patients with autoimmune PAP show decreased PU.1 messenger RNA (mRNA), which is thought to be central to the pathogenesis of PAP. PU.1 has been shown to regulate Toll-like receptor (TLR) signaling, adhesion, phagocytosis, and microbicidal activity, thus providing a mechanism for the increased infection susceptibility that is observed in PAP. Beyond the macrophage, defects have also been shown in neutrophil adhesion, phagocytosis, oxidative burst, and bacterial killing from both the blood of human patients with PAP and GM-CSF$^{-/-}$ mouse bone marrow.[15]

Patients with acquired PAP are vulnerable to typical respiratory pathogens as well as opportunistic infections. Although the high incidence of respiratory infections may be partially attributable to their underlying chronic lung disease, the opportunistic infections are generally caused by organisms controlled by macrophages, including *Nocardia, Histoplasma*,[1] nontuberculous mycobacteria,[16] and *Cryptococcus.*[17] Although Witty et al. reported eight cases of PAP and *Mycobacterium avium* complex cultured from BAL fluid,[16] these patients did not receive antimycobacterial drugs and appeared to fare no worse. Furthermore, most of these infections were described before the recognition of anti–GM-CSF autoantibodies as being causal, so these reports may be confounded by heterogeneity within the underlying diagnosis.

Extrapulmonary infections have been observed with some frequency, which could be ascribed to the systemic effects of anti–GM-CSF autoantibodies identified in serum. In support of this systemic effect, several case reports describe patients with PAP who had extrapulmonary infections, including cases of central nervous system (CNS) *Nocardia infection,* septic arthritis, perinephric abscess, and *Nocardia* dissemination to skin; CNS *Aspergillus* and *Proteus;* and disseminated histoplasmosis.[1] Recently, a few case series have reported opportunistic infections associated with high-titer neutralizing anti–GM-CSF autoantibodies without concurrent PAP. Anti–GM-CSF antibodies have been reported in previously healthy adults uninfected by HIV who had cryptococcal meningitis specifically caused by *Cryptococcus gattii.*[17,18] Neutralizing anti–GM-CSF autoantibodies were also found in five of seven patients with disseminated/extrapulmonary *Nocardia* infections.[19] However, it remains to be seen if these infections are the only manifestations in these patients or they may eventually develop PAP as seen in the two of seven cases of cryptococcal meningitis associated with anti–GM-CSF autoantibodies.[17] Why the same autoantibody may have different clinical phenotypes is unknown. Opportunistic infections have not been reported as a complication of congenital PAP. Reasons for this could include the extreme rarity of this condition or limited opportunity for exposure to environmental opportunists as a result of medical debilitation.

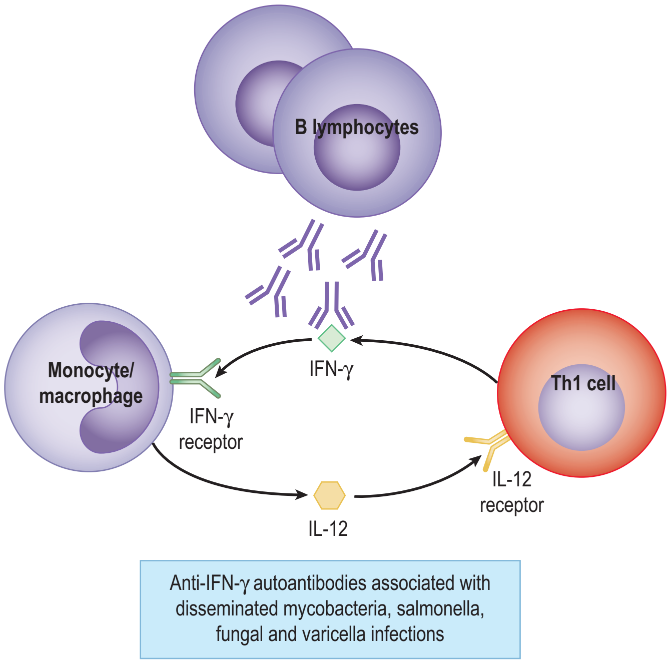
Treatment includes whole lung lavage to evacuate the proteinaceous material contained in the alveoli. Inhaled and subcutaneous GM-CSF has also been effective either by saturating the antibody or inducing tolerance.[20,21] In two large studies, one using subcutaneous GM-CSF and one using inhaled GM-CSF, a clinical response was not associated with a reduction in plasma or BAL concentrations of anti–GM-CSF autoantibodies, thereby providing possible support for the former mechanism.[20,21] B-cell–targeted therapy using the anti-CD20 chimeric monoclonal antibody (mAb) rituximab has been used to treat a small number of patients and has shown encouraging clinical results.[22]

ANTI–IFN-γ AUTOANTIBODIES AND SUSCEPTIBILITY TO INTRACELLULAR PATHOGENS

IFN-γ, produced predominantly by activated Th1 cells and natural killer (NK) cells, is central to host defense against intracellular pathogens (Chapter 26). The IFN-γ receptor (IFN-γR), expressed primarily on monocytes, is composed of two subunits in duplicate, IFN-γR1 and IFN-γR2. Binding of IFN-γ to its receptor leads to Janus kinase 2 (JAK2) and then JAK1 phosphorylation on the intracellular portions of IFN-γR2 and -1, respectively. Subsequent STAT-1 docking, phosphorylation, homodimerization, and nuclear translocation lead to transcription of IFN-γ responsive genes. Macrophage activation, differentiation, and elaboration of inflammatory mediators, such as tumor necrosis factor-α (TNF-α) and IL-12, ensue. Defects in the IFN-γ–IL-12 axis lead to mendelian susceptibility to mycobacterial disease as well as those caused by other intracellular pathogens, including listeriosis, salmonellosis, histoplasmosis, melioidosis, and penicilliosis.[23] The list of genetic mutations involving this pathway that result in increased susceptibility to mycobacteria or other intracellular pathogens continues to expand and, to date, includes mutations in IFN-γR1, IFN-γR2, STAT1, IL-12p40, IL-12Rb1, nuclear factor-κB (NF-κB) essential modulator (NEMO), IFN regulatory factor (IRF) 8, and IFN-stimulated gene (ISG) 15.[23] Neutralizing autoantibodies against IFN-γ represent an alternative mechanism by which the IFN-γ–IL-12 metabolic pathway is disrupted, with the first cases described in 2004[9] (Fig. 40.2). We reported 85 patients identified in a 6-month period,[2] with over 130 patients reported to date,[8-12] and this suggests that immunodeficiency caused by anti–IFN-γ autoantibodies is probably underappreciated.

The infections in patients with anti–IFN-γ autoantibodies mimic many of those seen in patients with inborn errors in the IL-12–IFN-γ signaling pathways and include mycobacterial, particularly nontuberculous environmental mycobacteria, nontyphoidal *Salmonella, Penicillium, Histoplasma, Cryptococcus, Burkholderia pseudomallei,* and additionally varicella-zoster virus (VZV), both dermatomal and disseminated.[2] Infections have been noted in all organ systems, although lymph nodes, skin, soft tissue, and bone appear to be preferentially affected. Up to 50% of patients develop sterile reactive dermatoses, most commonly neutrophilic dermatosis, but also erythema nodosum, pustular psoriasis, and exanthematous pustulosis.

Although patients with mendelian defects tend to present in childhood, all reported cases of patients with anti–IFN-γ were previously healthy adults, the vast majority of whom were Asian-born Asians. A recent association with human leukocyte antigen–antigen D related (HLA-DR)*15:02/16:02 and HLA-DQ*05:01/05:02 was shown in 78 patients with anti–IFN-γ autoantibodies,[24] further implicating a genetic predisposition to development of disease. However, no familial clustering has been observed, and Asians born outside of Asia have yet to be reported with this syndrome, suggesting complex genetics and possibly an environmental contribution to autoantibody pathogenesis. The recent report of an American-born, Caucasian female with this syndrome also adds to the complexity of its pathogenesis.[12]



Anti-IFN-γ autoantibodies associated with disseminated mycobacteria, salmonella, fungal and varicella infections

FIG 40.2 Anti-Interferon (IFN)γ Autoantibody Associated Susceptibility to Intracellular Pathogens. Neutralizing autoantibodies against IFN-γ disrupt the IFN-γ–IL-12 metabolic pathway. Infections in patients with anti–IFN-γ autoantibodies mimic many of the infections seen in patients with inborn errors in the interleukin (IL)-12–IFN-γ signaling pathways and include mycobacterial, nontyphoidal *Salmonella, Penicillium, Histoplasma, Cryptococcus, Burkholderia pseudomallei,* and varicella zoster virus. Th1 cell, T-helper cell-1.

Notable laboratory features include anemia of chronic disease and elevation in inflammatory markers, such as erythrocyte sedimentation rate (ESR), CRP, and β_2 microglobulin. Immunologically, patients commonly demonstrate polyclonal hypergammaglobulinemia, but they otherwise have normal lymphocyte phenotyping, including CD4 T lymphocytes, monocyte numbers, and IFN-γR1 expression.

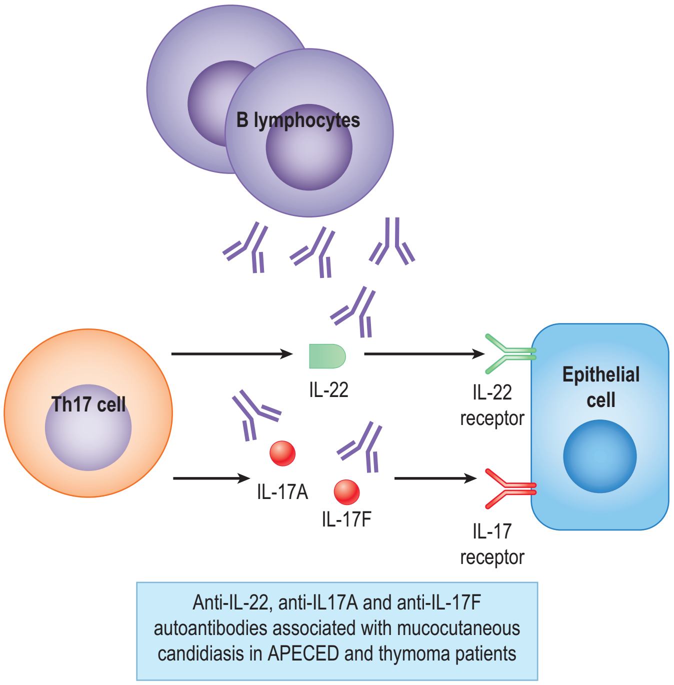
Treatment has focused mainly on managing the infections with targeted antimicrobials. Interestingly, a severe paradoxical inflammatory reaction similar to immune reconstitution syndrome, manifesting as lymphadenopathy, cavitary lung lesions, and lytic bone lesions during antituberculosis treatment, has been reported and should be distinguished from true failure of antimicrobial treatment.[25] In cases refractory to antiinfective agents, some have attempted to overcome the antibody with IFN-γ administration or drive down antibody levels with plasmapheresis and cyclophosphamide[26] or rituximab.[8] It is unclear what factors predict response to antimicrobials alone versus a need for further immunomodulation; the efficacy of these immune modulatory approaches remains to be evaluated formally in clinical trials.

ANTI–IL-17 AND ANTI–IL-22 AUTOANTIBODIES AND CHRONIC MUCOCUTANEOUS CANDIDIASIS

IL-17A and IL-17F are proinflammatory cytokines that can combine as either homodimers or heterodimers with each other (Chapter 9). These dimerized combinations signal via IL-17RA and IL-17RC heterodimeric receptor complexes, ultimately activating NF-κB. IL-22, produced by T lymphocytes and NK cells, also signals via a heterodimeric receptor composed of IL-22R1 and IL-10R2 subunits, expressed mainly on epithelial and other nonimmune cells. IL-17A/F and IL-22 cooperate to induce proinflammatory cytokines involved in granulopoiesis and neutrophil recruitment as well as antimicrobial peptides, such as β defensins and S100 proteins, which are thought to be important in mucosal immunity. Clinical evidence for a protective role of IL-17 in CMC arose from the observation of this infectious complication in diseases with varying degrees of Th17 impairment, including *STAT3*-deficient hyper-IgE syndrome (HIES, or Job's syndrome), dectin-1 deficiency, CARD9 deficiency, and, to a lesser degree, IL-12 receptor β_1 deficiency.[27] Strong support of this hypothesis came via instances of two families that demonstrated inherited susceptibility to mucosal candidiasis: one with an autosomal recessive mutation in IL-17RA, and another with an autosomal dominant negative mutation in IL-17F.[27]

APECED syndrome is another mendelian disorder associated with CMC. APECED, caused by mutations in the *AIRE* gene, leads to a clinical triad of hypoparathyroidism, adrenal insufficiency, and CMC.[13] Other endocrine glands, including gonads, thyroid, endocrine cells in the gut, and pancreatic islet cells, are variably affected. Many other autoimmune phenomena, including Sjögren syndrome, rheumatoid arthritis, hepatitis, keratitis, vitiligo, pernicious anemia, and alopecia, as well as autoantibodies to type I IFNs, have been described.[13] The biological consequences of these anti–IFN-α autoantibodies are unclear, but autoantibodies to other tissue antigens in autoimmune polyendocrinopathy syndrome type 1 (APS-1), such as autoantibodies to glutamic acid decarboxylase, thyroid peroxidase, and 21-hydroxylase, are clearly pathological. Providing explanation for the preponderance of autoimmunity seen in APECED was the observation that the transcriptional activity of AIRE in medullary thymic epithelial cells (mTECs) promotes expression of tissue-specific genes, thereby facilitating intrathymic destruction of autoreactive T cells and fostering self-tolerance.[13]

Unlike the above-described mendelian disorders, the mechanism of CMC in APECED is not directly linked to the genetic deficiency itself but, rather, to the strong genetic predisposition to autoimmunity, which, in this case, includes production of neutralizing anti–IL-17A, anti–IL-17F and anti–IL-22 autoantibodies[3,4] (Fig. 40.3). Puel et al. identified antibodies to IL-17A, IL-17F, or IL-22 in 33 patients with APECED, 29 of whom also had CMC, compared with healthy controls who had neither autoantibodies nor CMC.[4] Kisand et al. found anti–IL-17A, –IL-17F, or –IL-22 autoantibodies in up to 90% of 162 cases, also strongly associated with CMC.[3] They also identified anti–IL-17 and anti–IL-22 autoantibodies in two patients with thymoma and CMC, but in none of the 33 patients with thymoma who did not have CMC. There were a few instances of autoantibodies without CMC, and there are many examples of CMC independent of APECED, and this suggests that autoantibodies to IL-17 and IL-22 are not absolutely necessary for development of CMC. However, their identification, particularly in light of the CMC disease seen in patients with IL-17RA and IL-17F mutations, provides support for a causal relationship. Interestingly, thymoma tissue also demonstrates decreased AIRE expression, further linking these diseases beyond a shared tendency toward autoimmunity and anticytokine–autoantibody production. What is less clear however, is the exact role AIRE is playing in pathogenesis of organ-specific autoimmunity (including anticytokine autoantibody



Anti-IL-22, anti-IL17A and anti-IL-17F autoantibodies associated with mucocutaneous candidiasis in APECED and thymoma patients

FIG 40.3 **Anti–Interleukin (IL)-17 and Anti–IL-22 Autoantibodies Associated Chronic Mucocutaneous Candidiasis (CMC).** IL-17A/F and IL-22 induce proinflammatory cytokines involved in granulopoiesis and neutrophil recruitment as well as important mucosal antimicrobial peptides, such as β defensins and S100 proteins. Neutralizing anti–IL-17A, anti–IL-17F, and anti–IL-22 autoantibodies in autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia (APECED) syndrome is the likely mechanism of CMC in these patients.

formation), since the syndromes diverge considerably in this regard.[13]

ANTI–IL-6 AUTOANTIBODIES AND RECURRENT STAPHYLOCOCCAL SKIN INFECTION

IL-6 is produced by many immune and nonimmune cells, including B cells, T cells, macrophages, synovial cells, endothelial cells, and hepatocytes, and is involved in both acute and chronic inflammation, ranging from sepsis to rheumatoid arthritis. IL-6 binds a heterodimeric receptor composed of IL-6Rα and a shared receptor chain gp130. IL-6Rα confers ligand specificity, whereas gp130 mediates signal transduction. IL-6 regulates the acute phase response in the liver, with its hallmark induction of CRP and elevated ESR. Anti–IL-6 autoantibodies were identified in a Haitian boy who had two episodes of severe staphylococcal cellulitis, one complicating chickenpox infection, the other complicating mosquito bites.[5] Treatment included supportive care and antiinfective agents. Undetectable CRP, despite severe infection, suggested impairment in IL-6 activity. STAT3 is the critical signal transduction molecule for IL-6 and IL-10, and autosomal dominant mutations in *STAT3* also lead to recurrent staphylococcal skin abscesses,[28] suggesting a common potential mechanism for this phenotypic profile of infection susceptibility. The limitations to this association are that the infections in the Haitian boy resolved without any apparent change in the anti–IL-6 autoantibody titers, and this is the only reported case to date.

MANAGEMENT

Therapies directed at the syndromes of pathogenic autoantibodies have focused either on treating the disease consequences or targeting the autoantibody itself. Therapeutic BAL removes proteinaceous alveolar material from the lungs of patients with PAP,[1] and antimycobacterials treat the disseminated NTM infection in patients with autoantibodies to IFN-γ.[9,29] Approaches ranging from physical removal of the antibody, to immunomodulatory therapy, to induction of immune tolerance or suppression of the population of cells that produce the pathogenic autoantibodies have also been employed.

PAP and disseminated NTM associated with anti–IFN-γ autoantibodies have been treated with exogenous GM-CSF[20,21] and IFN-γ,[29] respectively, resulting in clinical improvement, although PAP has been studied more rigorously in this regard. Autoantibody levels after therapy were not routinely evaluated across diseases, nor are they performed in a standardized fashion, although, at least in the PAP cohorts, it appears they do not change in response to exogenous cytokine.[20,21]

In cases that are refractory to treatment, attempts have been made to alleviate the blockade by reducing anticytokine–autoantibody levels. One patient with anti–IFN-γ autoantibodies underwent plasmapheresis and cyclophosphamide therapy in addition to antimycobacterials.[26] Rituximab, the mouse–human chimeric mAb that targets the human B-cell marker CD20, is currently approved for treatment of B-cell lymphoma and rheumatoid arthritis. Since B cells ultimately differentiate into antibody-producing cells, it has been applied to a number of autoantibody-mediated diseases, such as myasthenia gravis (Chapter 65) and pemphigus vulgaris (a blistering skin disease caused by autoantibodies that recognize desmoglein 3, a keratinocyte cell-surface protein; Chapter 63). Successful rituximab therapy has also been reported in PAP[22] and immunodeficiency caused by anti–IFN-γ autoantibodies[8] with a specific reduction of anticytokine–autoantibody titers.

A new approach in pure red blood cell (RBC) aplasia caused by antierythropoietin autoantibodies is to bypass the autoantibody with a erythropoietin receptor synthetic peptide agonist peginesatide (Hematide; Affymax) that does not share homology with the eosinophil peroxidase (EPO) ligand.[30] Although this approach has not been used in cases of anticytokine autoantibodies and immune deficiency, it underscores the range of novel treatment approaches that might be explored for anticytokine autoantibody–associated syndromes.

CONCLUSIONS

Anticytokine autoantibodies have been identified in healthy normal adults as well as in those with different diseases, suggesting that their occurrence may range from a normal homeostatic mechanism, to epiphenomena, to being directly pathogenic. In PAP, the identification of anti–GM-CSF autoantibodies came over 40 years after the initial description of the syndrome, suggesting that other currently idiopathic diseases may someday be explained by the identification of neutralizing or agonizing autoantibodies. Furthermore, it was not intuitive that systemic autoantibodies to a hematopoietic growth factor should result in disease confined mainly to the lung. The identification of anti–GM-CSF autoantibodies in cryptococcal meningitis implicates the GM-CSF pathway in host defense of this infection, much as mendelian disorders have done for NTM and the

ON THE HORIZON

- Anticytokine autoantibodies are an emerging mechanism underlying the pathogenesis of immune deficiency in previously “healthy” adults.
- The clinical manifestations of these diseases, like pulmonary involvement in anti–granulocyte macrophage–colony-stimulating factor (GM-CSF) associated pulmonary alveolar proteinosis (PAP), may provide insight to signaling pathways and target cells of the involved cytokine.
- Recent discovery of many anticytokine autoantibody–associated diseases suggests that other idiopathic immunodeficiency diseases may be the result of an autoantibody affecting an as-yet unknown signaling pathway or cell type.
- Much research needs to be done on the management of patients with these syndromes, since besides just treating the symptomatic consequences of the autoantibody, the autoantibody or its generation itself can now be targeted.
- Profiling anticytokine autoantibodies in patients with immunodeficiency could help personalize their management by potentially predicting disease manifestations and optimizing treatment options.

IFN-γ–IL-12 pathway. The observation of high-titer, neutralizing anticytokine autoantibodies in an expanding number of diseases, beyond just those characterized by immune deficiency,[7] combined with the opportunity for novel therapeutic approaches to their diagnoses, mandates that their presence be not merely considered but rigorously sought.

MULTIPLE-CHOICE QUESTIONS

1. High-titer, neutralizing autoantibodies against which cytokine is commonly seen in autoimmune polyendocrinopathy candidiasis ectodermal dystrophy (APECED) syndrome?
   - **A.** Interferon (IFN)-α
   - **B.** IFN-γ
   - **C.** Granulocyte macrophage–colony-stimulating factor (GM-CSF)
   - **D.** Interleukin (IL)-6

2. A 45-year-old female who moved from Taiwan to the United States at the age of 20 years presents with disseminated *Mycobacterium abscessus* with pulmonary and bone lesions and cervical lymphadenopathy. Autoantibodies to which cytokine may be associated with her disease?
   - **A.** IL-17
   - **B.** IL-22
   - **C.** IFN-α
   - **D.** IFN-γ

3. A previously healthy HIV-negative 34-year-old woman presented with few days of fever, headache, neck pain, and vomiting. She also reported progressively increasing exertional dyspnea since the past 6 months. Lumbar puncture showed increased opening pressure. Cerebrospinal fluid (CSF) analysis revealed increased white blood cell (WBC) count with lymphocytic predominance, low glucose, and elevated protein. The CSF cryptococcal antigen was positive, and the culture grew *Cryptococcus neoformans.* Brain magnetic resonance imaging (MRI) was normal. Chest computed tomography (CT) showed ground-glass opacities in both lungs. Bronchoalveolar lavage (BAL) revealed periodic acid-Schiff (PAS)–positive material on cytology, consistent with a diagnosis of pulmonary alveolar proteinosis (PAP). Autoantibodies against which cytokine may be associated with her manifestations?
   - **A.** GM-CSF
   - **B.** IL-6
   - **C.** G-CSF
   - **D.** Erythropoietin
   - **E.** IFN-γ

Immunological Mechanisms of Airway Diseases and Pathways to Therapy

David B. Corry, Farrah Kheradmand, Amber Luong, Lavannya Pandit

The immunological airway diseases comprise a large and disparate group of respiratory disorders characterized by airway and parenchymal inflammation that impairs sinus and lung function. The physiological importance of the airways, combined with the need to respond immunologically to an extremely broad range of particulate and gaseous aerosols, explains much of the diverse nature of airway immune disorders and their disproportionately large effect on human health. The allergic respiratory tract immune disorders covered in this chapter are among the most common of all human afflictions.

Allergic disorders have a common immune phenotype comprising highly characteristic cellular, humoral, biochemical, and molecular components, although individual variability means that not all these immunological features are equally expressed. The most studied and visually characteristic allergic immune cells are eosinophils and tissue mast cells, which are easily seen on conventional hematoxylin and eosin (H&E) staining of pathological specimens. Eosinophils may far outnumber all other inflammatory cells. Less obvious on histochemical staining, but equally important to allergic diseases, are B cells that secrete the antibody isotypes immunoglobulin E (IgE) and IgG4, and T-helper 2 (Th2) cells, which secrete a restricted repertoire of cytokines, including interleukin-4 (IL-4), -5, -9, -10, and -13, which coordinate and activate other allergic effector cells, such as innate lymphoid cells (ILCs).

The allergic airway diseases are typically chronic and occasionally fatal; although spontaneous remissions are not uncommon, the conditions are rarely curable. Recent insights into pathophysiological mechanisms have, however, opened up new prospects for improved therapy.

CLINICAL PRESENTATION OF ALLERGIC AIRWAY DISEASE

Although the diverse effector cells and molecules that characterize allergic inflammatory exudates may be seen at any point along the respiratory tract, the functional impact of allergic disease is quite different in the upper and lower airways.

Chronic Rhinitis and Rhinosinusitis

Epidemiology and Clinical Presentation

The major upper airway inflammatory disorders are rhinitis and chronic rhinosinusitis. Allergic rhinitis (AR) involves inflammation of the nasal mucosa: it is the most common type of chronic rhinitis affecting approximately 50 million Americans. In different surveys, AR accounts for 30–70% of chronic perennial rhinitis, with the balance being nonallergic. Typical symptoms of AR include clear rhinorrhea, sneezing, postnasal drip, nasal pruritus, and congestion, often in association with ocular symptoms, such as conjunctivitis and tearing. Based on symptom duration, AR is now classified as "intermittent" or "persistent," with severity of symptoms noted as "mild" or "moderate to severe."[1] Consequently, AR can be categorized into four groups based on the combination of above two categories of frequency and symptom severity. Patients with persistent AR typically have daily symptoms all year round but can also show seasonal fluctuations in the severity of their symptoms. The impact of symptoms on quality of life and on productivity is reflected in the "mild" and "moderate–severe" categorization.

KEY CONCEPTS

Classification of Allergic Rhinitis

Frequency of Symptoms	Severity of Symptoms
Intermittent	**Mild**
Symptoms present for <4 days a week	No presence of sleep disturbance
Or for <4 weeks	Or impairment of daily activities, leisure, and/or sport
	Or impairment of school or work
	Or troublesome symptoms
Persistent	**Moderate-Severe**
Symptoms present for >4 days a week	Presence of sleep disturbance
Or for >4 weeks	And/or impairment of daily activities, leisure, and/or sport
	And/or impairment of school or work
	And/or troublesome symptoms

In contrast to rhinitis, which involves inflammation and symptoms confined to the nasal passages and mucosa, rhinosinusitis (RS) affects both the sinuses and the nasal mucosa. Rhinosinusitis can be subdivided into acute and chronic rhinosinusitis (CRS), based on duration of symptoms. CRS is reported to affect approximately 29 million Americans and is defined by symptoms persisting for longer than 12 weeks. Clinically, CRS is subdivided on the basis of the presence or absence of nasal polyps. Within CRS with nasal polyps (CRSwNP), there are several recognized clinical subtypes, including allergic fungal rhinosinusitis (AFRS), aspirin-exacerbated respiratory disease (AERD), and cystic fibrosis.[2]

Signs and symptoms associated with RS in adults include facial pain and pressure, headaches, nasal congestion with or without obstruction, frontal or post nasal drainage, generalized malaise, loss of sense of smell (hyposmia), and cough. Of these, nasal obstruction is the most common (81–95%), followed by facial pain and pressure (70–85%), discolored nasal drainage (51–83%), and hyposmia (61–69%). In contrast, symptoms in children vary with age and require the parent or caregiver to recognize them. Young children often present with a chronic cough and irritability, rather than facial pain. Parents often also report the child has halitosis and purulent nasal discharge. Although it is more difficult to determine the prevalence of RS in children because of overlapping symptoms with AR and viral upper respiratory tract infections, its prevalence is inversely related to age.[2]

Diagnosis

The diagnosis of AR is based on a history of typical symptoms and physical examination findings. Common symptoms include postnasal drainage, sneezing, itchy nose and eyes, and clear rhinorrhea. The frequency and effect of symptoms on sleep and productivity should be assessed to classify the AR as intermittent or persistent and mild or moderate–severe.

Patients suffering from AR can present with an "allergic shiner," a darkening of the infraorbital skin resulting from chronic venous pooling. In some children, wiping the front of the nose with the back of the hand in an upward motion (the allergic salute) creates a persistent horizontal crease across the nasal bridge that is a hallmark of chronic anterior rhinorrhea. Bilateral conjunctivitis may be present in patients along with ocular involvement.

On anterior rhinoscopy with a hand-held otoscope, engorged, boggy, and pale inferior turbinates also suggest AR. In addition, there is often a clear discharge coating the nasal cavity. Examination of the oropharynx often reveals cobblestoning of the mucosa, a sign of chronic postnasal drip.

Although not necessary to make the diagnosis of AR, two tests commonly used to demonstrate IgE-mediated allergic reactions are immediate-hypersensitivity skin testing and measurement of serum allergen–specific IgE levels. Skin prick tests correlate well with the symptoms of allergic rhinitis and with airway responsiveness to allergens, and measuring serum allergen-specific IgE levels provides an *in vitro* means of supporting a diagnosis of AR. Compared with skin prick testing, the *in vitro* test is more specific but less sensitive and can be more expensive.[3] However, serum tests may be the only practical way of detecting allergen-specific IgE in some patients, especially those with urticaria and eczema.

The diagnosis of CRS requires the presence of at least two major symptoms or one major and at least two minor clinical symptoms persisting for longer than 12 weeks, in conjunction with objective evidence of inflammation within the sinus cavity. The major symptoms include facial pain or pressure, nasal obstruction, nasal drainage, and hyposmia or anosmia. Minor symptoms are headaches, halitosis, fatigue, dental pain, cough, and ear pain or pressure. The most specific symptom for RS is discolored nasal discharge.[4] Since most symptoms of rhinosinusitis are nonspecific, evidence of inflammation on nasal endoscopy or imaging is also necessary to make a diagnosis of CRS. On nasal endoscopy, inflammation is suggested by edema and/or drainage from the middle meatus; CRSwNP is diagnosed when nasal polyps are visualized (Fig. 41.1). Inflammation within the sinuses may not be apparent on nasal endoscopy: in patients with a strong history of CRS, computed tomography (CT) of the sinuses is necessary to detect mucosal thickening and/or fluid within the sinuses (Fig. 41.2).

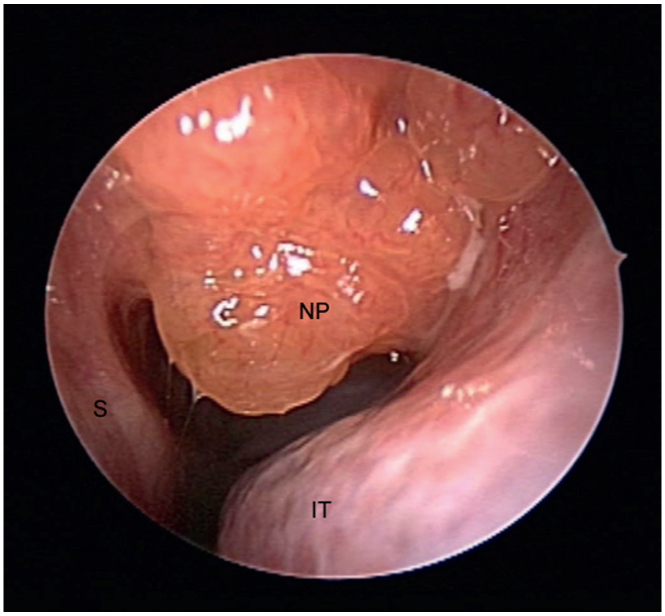

FIG 41.1 Nasal Polyposis. Seen on this nasal endoscopy are nasal polyps (NP) emanating from the sinus cavity into the nasal cavity between the septum (S) and the inferior turbinate (IT) of a patient with chronic rhinosinusitis.

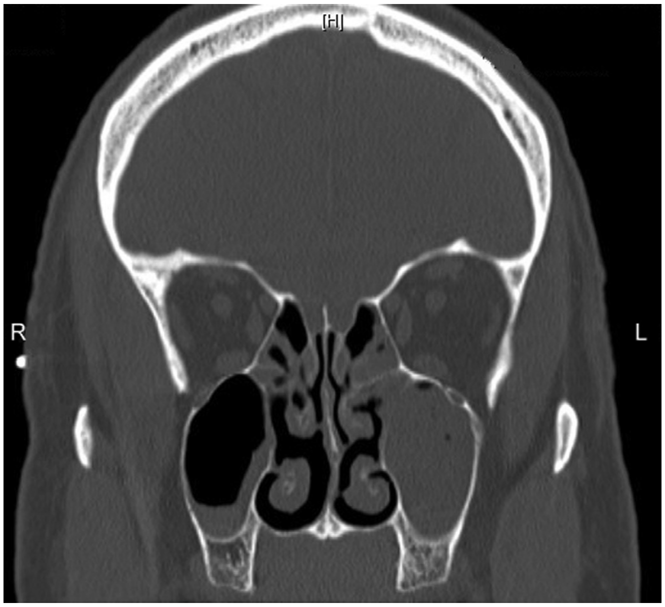

FIG 41.2 Coronal Sinus Computed Tomography (CT) Image From a Patient With Chronic Rhinosinusitis. The maxillary sinuses (lateral to the nasal cavity) and ethmoid sinuses (medial to the orbital cavities) exhibit mucosal thickening and accumulation of obstructed secretions consistent with inflammatory changes within the paranasal sinuses.

To make the diagnosis of AFRS, the most widely accepted diagnostic criteria include five characteristics: nasal polyps; type I (immediate) hypersensitivity to fungi; radiographic imaging consistent with AFRS; eosinophilic mucin with evidence of fungi; and lack of evidence of fungal invasion into the surrounding sinus tissue. Type I hypersensitivity to fungi can be detected by positive skin testing to fungal antigens or elevated serum fungal-antigen-specific IgE titers. Imaging consistent with AFRS is obtained by CT and magnetic resonance imaging (MRI). Fulfilling the remaining criteria for AFRS requires histological examination and microbiology for fungi within the mucin and tissue obtained at the time of surgery.[5]

KEY CONCEPTS

Diagnosis of Chronic Rhinosinusitis (CRS)

Chronic Rhinosinusitis

- Presence of at least two of the following symptoms:
  - Facial pressure or pain
  - Nasal obstruction or congestion
  - Anterior or posterior nasal drainage
  - Hyposmia or anosmia
- Edema or discolored drainage within the sinus cavity or middle meatus
- *Or* CT sinus showing fluid or mucosal thickening within sinus cavities

CRS Without Nasal Polyps	CRS With Nasal Polyps
No evidence of nasal polyps within the middle meatus as noted on nasal endoscopy in a patient with no history of previous sinus surgery	Presence of nasal polyps within the middle meatus as noted on nasal endoscopy
	History of nasal polyps within sinus cavity in a previously operated patient with CRS diagnosis

The diagnosis of AERD requires meeting diagnostic criteria for nasal polyps and asthma, along with a history of respiratory symptoms exacerbated by oral intake of aspirin or other cyclooxygenase-1 (COX-1) inhibitors on at least two occasions, or a positive reaction on aspirin challenge.[6]

Cystic fibrosis is typically diagnosed in early childhood as a result of pulmonary symptoms. However, the presence of nasal polyps in anyone under 18 years should prompt an evaluation for cystic fibrosis, which is confirmed either by sweat test or by demonstrating a mutation in the cystic fibrosis transmembrane conductance regulator gene.

Therapy

The most effective and widely used drugs for controlling the nasal and ocular symptoms of AR are glucocorticosteroids and antihistamines. Intranasal glucocorticosteroids (steroids) are the most efficacious medication class available for the management of AR symptoms, particularly nasal congestion, and are considered first-line medical therapy. They may also improve eye symptoms. Of the numerous formulations available, mometasone furoate demonstrates the highest antiinflammatory potency and lowest systemic absorption compared with other commonly used intranasal steroids. However, no studies have shown any differences in clinical efficacy among the currently available intranasal steroids.[7]

Oral antihistamines are also highly effective against the histamine-driven symptoms of sneezing, pruritus, and rhinorrhea. Second-generation antihistamines are recommended over first-generation formulations for their lack of sedating effects and equivalent ability to reduce AR symptoms. Intranasal antihistamines can be as effective as oral antihistamines for control of allergic and nonallergic rhinitis, but neither is as effective as intranasal steroids for nasal congestion. Other pharmacological agents potentially useful in the management of rhinitis include oral steroids, oral leukotriene (LT) receptor antagonists, intranasal chromones, and intranasal ipratropium bromide.[8]

In addition to pharmaceutical approaches, allergen immunotherapy offers a means of providing long-term relief from rhinitis (Chapter 91). Two types of immunotherapy are available: subcutaneous immunotherapy (SCIT) and sublingual immunotherapy (SLIT). An important concern associated with the use of SCIT is anaphylaxis, whereas this risk is probably much lower with SLIT. The antigens for SLIT are available in both liquid formulation, which allows for customized combinations, and preformed tablets. Finally, intensive home and workplace remediation directed at limiting allergen exposure is potentially beneficial in those with demonstrable environmental allergies.[8]

The treatment of CRS is more controversial than that of AR. In general, treatment can consist of either medical or surgical therapy. CRS is currently viewed as primarily an inflammatory, rather than an infectious, disorder such that antibiotics are less frequently advocated and have largely been replaced with intranasal and oral antiinflammatory agents, such as steroids. In addition, daily sinus irrigations with physiological saline can counteract mucociliary dysfunction and promote antigen clearance.

Future therapies for CRS are likely to include biologics aimed at the key cytokines, molecules, and cells that are important in the type 2 inflammatory responses which characterize CRSwNP. These potential therapeutic targets include IL-33, IL-25, thymic stromal lymphopoietin (TSLP), IL-5, IL-4, IL-13, siglec-8, and IgE. However, these treatment options will require a more sophisticated classification of CRS beyond the basis of nasal polyps. Endotyping based on immunological, molecular, or histological characteristics represents the future of CRS classification. We also need to better understand the role that environmental fungi play in triggering the inflammatory cascade leading to particular CRSwNP subtypes and allergic asthma. The use of antifungals in CRS seems logical, given the strong association between CRS and fungi, including yeasts and molds.[9] This has been investigated through many clinical trials, most of which are methodologically weak, failing to specify which patients actually have fungal infection or at least fungal sensitivity and lacking adequate control populations. Despite these limitations, the existing studies suggest that topical antifungal antibiotics (*e.g.*, amphotericin B) are not effective, whereas systemic antifungals may significantly inhibit recurrent disease.[10]

Patients with persistent symptoms despite medical therapy may benefit from functional endoscopic sinus surgery (see Video 1 online). Outcomes of medical therapy versus sinus surgery combined with intranasal steroids showed similar improvements, but patients with CRSwNP achieved improved asthma control with medical therapy. Endoscopic sinus surgery is mandatory for patients with AFRS in whom the sinuses are impacted with copious thick mucus requiring manual extraction and patients presenting with serious complications of CRS, such as vision loss or intracranial extension of disease.

Asthma

Epidemiology and Clinical Presentation

After several decades of rising incidence, asthma is now the most common chronic disease of childhood and one of the most common disorders of adults in the United States. Although most frequently diagnosed initially in childhood, asthma can be first diagnosed at any age. The widely prevalent and incurable nature of asthma will continue to assure its position as one of the most costly of medical afflictions both in terms of total medical expenditure and in time lost from work and school. Asthma is a lower respiratory tract disease that is characterized by dyspnea and other symptoms, including cough, chest tightness, chest pain, and wheezing. Persons with mild disease often only have a mild, chronic cough. In contrast to other obstructive lung diseases, asthma symptoms are present intermittently and are characteristically relieved by bronchodilator and antiinflammatory therapy.

Patients with asthma are classified into distinct clinical subtypes according to characteristic environmental or occupational exposures that elicit disease symptoms, the presence or absence of concomitant atopy, temporal expression of symptoms, and responsiveness to antiinflammatory therapy. Respiratory viruses are the most frequently implicated causes of asthma attacks, especially in children, and tobacco smoke and air pollution are other major inciting agents. A large minority of patients with asthma have *atopy,* a term that reflects the production of IgE, a genetic predisposition toward immediate-type immune reactions, and symptoms on exposure to causative environmental agents, such as pollens, dust mites, fungi, and insects. If atopy is present, patients are referred to as having extrinsic, atopic, or allergic asthma, whereas those without atopy are referred to as having intrinsic or nonallergic asthma. In general, airway constriction occurs and symptoms of asthma are provoked when triggering agents are inhaled from the environment, representing the clinical expression of *airway hyperresponsiveness* (AHR)—the exaggerated tendency of the asthmatic airway to constrict in response to exposure to a wide variety of provocative agents. Some of these agents, such as viruses and pollens, are only intermittently present, causing seasonal asthma, whereas other agents are encountered continuously (*e.g.,* fungi) and cause persistent (or perennial) asthma. *Occupational asthma* is defined as asthma acquired in the workplace, where dozens of potentially toxic agents have been identified (Chapter 49). Numerous additional clinical subsets of asthma can be defined according to the factor or factors that most often elicit attacks of dyspnea. A final category of asthma, *steroid-resistant asthma,* refers to the condition in patients who are relatively unresponsive to antiinflammatory steroid therapy.

Diagnosis

Asthma is often recognized on clinical grounds alone, with acute attacks marked by obvious dyspnea, wheezing, cough, and use of accessory muscles of respiration. Such attacks typically resolve with bronchodilator therapy. Spirometry can provide more objective evidence of airway obstruction as assessed by reversible decrements in the forced expiratory volume per second (FEV_1) and other measures of air flow. Nonetheless, a uniformly acceptable disease definition has remained elusive, at least partly because of the nonspecific nature of symptoms and a clinical spectrum that blends with many other disease processes. When the clinical presentation is uncertain, bronchial provocation tests can be used to determine the presence of AHR and thereby establish the diagnosis.[11] Additional laboratory data that support a diagnosis of allergic asthma include peripheral blood eosinophilia, elevated serum total and antigen-specific IgE levels, and positive skin prick test results against one or more allergens.

Therapy

As with AR and RS, the therapy of asthma is generally nonspecific and directed at improving air flow through bronchodilation and reducing inflammation. Immediate relief of bronchoconstriction and dyspnea is achieved with bronchodilating agents that activate the β_2 adrenergic receptor on airway smooth muscle (β-agonists). For long-term control of asthma, the most effective agent class is glucocorticosteroids, which reduce inflammation and suppress airway constriction and dyspnea. For mild to moderate disease, bronchodilating agents and steroids are typically administered by inhalation, which reduces but does not eliminate systemic side effects. A secondary class of agents used for controlling bronchospasm comprises anticholinergics, which are antagonists of the muscarinic acetylcholine receptor. Severe disease may also require treatment with steroids, which are given orally or intravenously for relatively brief periods to minimize the often-severe side effects, and high-dose inhaled β-agonists, often given by nebulizer.

Additional antiinflammatory agents available for the treatment of asthma include LT receptor antagonists, chromones, theophylline, omalizumab (a monoclonal antibody [mAb] that reduces circulating and mast cell-bound IgE), and most recently mepolizumab (an anti–IL-5 antibody).[12] Bronchial thermoplasty (BT) is a relatively new bronchoscopic technique, in which heat is applied to the airways via a radiofrequency catheter to ablate smooth muscle cells. Although early clinical trials have been encouraging with regard to the ability of this technique to reduce exacerbation rates, further studies are required to understand the patient subgroups that are most likely to respond to these novel treatments.[13]

OTHER AIRWAY ALLERGIC DISEASE SYNDROMES

In addition to the common allergic disorders discussed above, several other allergic airway diseases have been described: although not as common, these often cause profound morbidity. As with asthma, these disorders are clinically heterogeneous but are believed to share a similar pathophysiology related to the inhalation of antigens that provoke airway eosinophil and Th2 responses. No single clinical, pathological, or radiographic feature is pathognomonic for these diseases, and diagnosis relies on a constellation of findings, especially antigen exposures, radiographic details, and histopathology. Nonetheless, all of these disorders are prominently linked by the presence of eosinophils in peripheral blood and airway tissues.

Under the trophic influence of IL-5, eosinophils develop from precursor cells present largely in bone marrow. Early mature eosinophils are then released into blood, where they circulate for a brief period before entering the interstitium of airway tissues, where they can reside for long periods. Chemotactic factors that enhance the extravasation of eosinophils include complement components, eosinophil chemotactic factor-A, LTs, tumor-associated factors, and chemokines. Putative functions of tissue resident eosinophils range from host defense against parasites, such as nematode helminths, in diseases, such as tropical pulmonary eosinophilia, to mediators of end-stage tissue destruction and irreversible lung damage and fibrosis in other disorders, such as acute and chronic eosinophilic pneumonia.

The eosinophilic disorders discussed below are organized according to whether there is an *extrinsic* or *intrinsic* cause of the eosinophilia (Table 41.1). Inhaled or ingested extrinsic factors, including medications and infectious agents (*e.g.,* parasites, fungi, mycobacteria), can trigger an eosinophilic immune response. This may be mild and self-limiting, as in Loeffler syndrome. Intrinsic pulmonary eosinophilic syndromes are, by definition,

TABLE 41.1 Eosinophilic Lung Disorders

Disease	Causative Agent	Proposed Immune Mechanism
Loeffler syndrome	Inhaled food, infection, or medication	T cell–mediated hypersensitivity reaction
Drug rash with eosinophilia and systemic symptoms (DRESS) syndrome	Drugs: sulfonamides, phenobarbital, sulfasalazine, carbamazepine, and phenytoin	Hypersensitivity reaction to drug
Parasitic infections	*Strongyloides* spp., *Wuchereria bancrofti, Brugia malayi*	T-cell and B-cell clonal activation in response to parasite antigens and adjuvant factors
Allergic bronchopulmonary aspergillosis	*Aspergillus*	Immunoglobulin E (IgE) and immune complex deposition
Acute eosinophilic pneumonia	Fungal infections, cigarette smoking, post–stem cell transplantation	Hypersensitivity response to inhaled antigen (infectious or otherwise)
Chronic eosinophilic pneumonia	Unknown systemic-mediated process	Unknown, but chronic nature evident with T cell–mediated granuloma production
Idiopathic hypereosinophilic syndrome	Infections, systemic diseases, and drugs that drive peripheral eosinophilia	Systemic responses caused, in part, by excess interleukin-5 (IL-5) production from clonal expansion of Th2 cells as well as fusion gene *FIP1L1–PDGFR*
Churg-Strauss syndrome	Autoimmune vasculitis to unknown antigen, associated with asthma	Decreased regulatory T-cell function with diminished IL-10 production

idiopathic and represent a varied group of diseases, often systemic in nature.

Extrinsic Eosinophilic Syndromes

Tropical Eosinophilic Pneumonias

The tropical eosinophilic syndromes are a group of clinically similar eosinophil-predominant inflammatory disorders characterized by chest pain, wheezing, cough, and AHR, often in the setting of a debilitating, but transient, febrile illness. Fleeting lung infiltrates may be seen on chest radiographs, and laboratory studies often demonstrate strikingly high peripheral blood, lung, and airway eosinophilia, as well as elevated serum IgE levels. Migrating parasites traversing the lungs are thought to be responsible for most cases of tropical eosinophilic pneumonia. Embolization of microfilariae (*e.g., Dirofilaria* spp.) or helminth eggs within the pulmonary microvasculature leads to antigen release and induction of a typically granulomatous allergic immune reaction. Persistent or chronic, recurrent infection with etiological organisms (*e.g., Strongyloides* spp. *Wuchereria bancrofti, Brugia malayi*) leads to chronic inflammation that may cause parenchymal necrosis and irreversible fibrosis. In the United States, *Strongyloides* spp. are the most common cause of parasitical infection and tropical eosinophilic pneumonia. Patients who are immunocompromised, including those recently prescribed systemic steroids, may develop *Strongyloides* hyperinfection syndrome, in which large numbers of recently released larvae burrow through the intestine and migrate to the lungs, causing a severe and potentially fatal lung disease that is frequently complicated by sepsis (Fig. 41.3). A very similar disease, termed *Loeffler syndrome,* was originally reported to be caused by the larvae of *Ascaris* spp., but other helminths and hypersensitivity responses to medications have since been etiologically implicated. Therapy of parasite-related pulmonary eosinophilia syndromes is directed at relieving symptoms and eliminating the parasites.

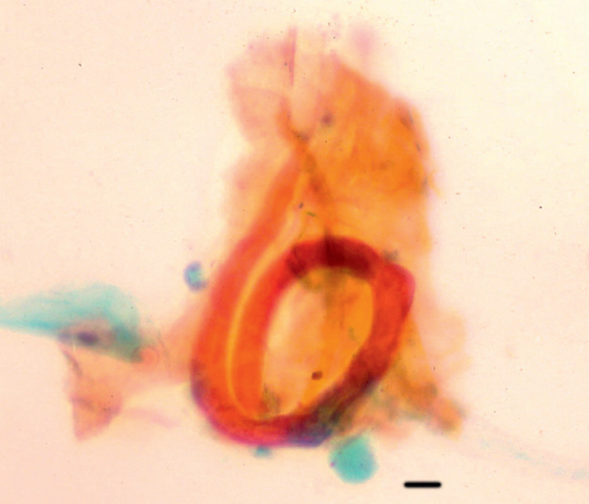

FIG 41.3 Strongyloidiasis. The coiled larva of *Strongyloides stercoralis* is seen on this Papanicolau stain of a bronchoalveolar lavage sample from a patient with *Strongyloides* hyperinfection. Original magnification ×400; bar = 10 µm.

DRESS Syndrome

The drug rash with eosinophilia and systemic symptoms (DRESS) syndrome is a severe drug hypersensitivity reaction that has a constellation of systemic signs and symptoms, including skin rash, fever, lymphadenopathy, and inflammation of the liver, lung, and heart (Chapter 48). Numerous drugs have been reported to cause DRESS syndrome, including sulfonamides, phenobarbital, sulfasalazine, and antiseizure medications, such as carbamazepine and phenytoin. Importantly, symptom onset may be delayed long after initiation of the drug.[14] The therapy of DRESS syndrome involves discontinuing the offending medication and providing supportive care in the setting of severe organ involvement.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis (ABPA) is a severe pulmonary allergic reaction to *Aspergillus* antigens that is seen almost exclusively in the setting of preexisting asthma or cystic fibrosis.[15] Diagnostic criteria include asthma with wheezing, peripheral blood eosinophilia, detection of precipitating anti-*Aspergillus* antibodies, elevated serum total IgE levels, and radiographic evidence of fleeting pulmonary infiltrates often accompanied by central bronchiectasis. *Aspergillus* spp. and other filamentous fungal species can frequently be isolated from airway secretions of patients with ABPA, suggesting that active fungal growth within the airways is responsible for the disease. Complications of chronic ABPA include severe AHR, severe bronchiectasis, eosinophilic pneumonia, pulmonary fibrosis, and invasive fungal disease.

Treatment of ABPA aims to suppress the inflammatory response to the fungus and to control bronchospasm with glucocorticoid therapy, the duration of which may be shortened by concomitant use of oral antifungal agents, such as itraconazole.[15]

Acute Eosinophilic Pneumonia

Acute eosinophilic pneumonia (AEP) is an acute, often debilitating eosinophilic inflammatory syndrome that exclusively involves the lungs and is marked by pulmonary infiltrates, dyspnea progressing to frank respiratory failure, and fever. The diagnosis is dependent on eosinophils exceeding 25% of all inflammatory cells within the bronchoalveolar lavage (BAL) fluid. Increasing evidence suggests an association between AEP and respiratory fungal infections and recent-onset cigarette smoking.[16,17] AEP has also been reported following allogeneic hematopoietic stem cell transplantation (HSCT) in the setting of graft-versus-host disease (GvHD).[18] Prompt recognition of the disease and initiation of treatment with glucocorticoids usually results in rapid radiographic and clinical improvement.

Intrinsic Eosinophilic Syndromes

Chronic Eosinophilic Pneumonia

This disorder presents similarly to AEP, but in a more chronic manner (greater than 6 weeks duration). Chronic eosinophilic pneumonia (CEP) can occur in isolation and/or in association with polyarteritis nodosa, rheumatoid arthritis, scleroderma, ulcerative colitis, breast carcinoma, and histiocytic lymphoma. Most patients have evidence of asthma and atopy. Like AEP, CEP can present with striking eosinophilic inflammation of the lung (Fig. 41.4). Granulomas are occasionally seen on biopsy specimens, suggesting that an antigen-driven, T cell–mediated process is involved in the chronicity of the disease. Treatment, as for AEP, is based on steroid therapy, but unlike AEP, CEP frequently relapses after discontinuation of treatment.[19]

Idiopathic Hypereosinophilic Syndrome

This multisystem disease is characterized by the massive accumulation of eosinophils in many tissues and almost always involves the lungs. Expansion of Th2 cells and local and systemic release of IL-4 and IL-5 are also frequently seen. The clonal expansion of Th2 cells in the absence of known antigen exposures, and the association of idiopathic hypereosinophilic syndrome (IHES) with a variety of chromosomal aberrations, strongly support the concept that IHES is a myeloproliferative disorder involving Th2 cells, although aberrant secretion of IL-5 by both solid and liquid tumors can produce very similar syndromes. Many organs can be affected, resulting in dysfunction or failure of the gastrointestinal (GI) tract, skeletal muscles (leading potentially to respiratory failure), endomyocardial fibrosis, myocarditis, and congestive heart failure. Pulmonary involvement manifests as obstructive airway disease, pulmonary edema, or pulmonary emboli caused by a hypercoagulable state. In addition to hypereosinophilia, patients with IHES may have evidence of polyclonal hypergammaglobulinemia. The diagnosis is based on the discovery of elevated peripheral blood eosinophilia in the setting of a multisystem disorder, with evidence of aberrant Th2 responses or elevated IL-5 secretion and defined genetic mutations. The most consistently effective therapy for IHES involves tyrosine kinase inhibition, using agents such as imatinib mesylate.[20]

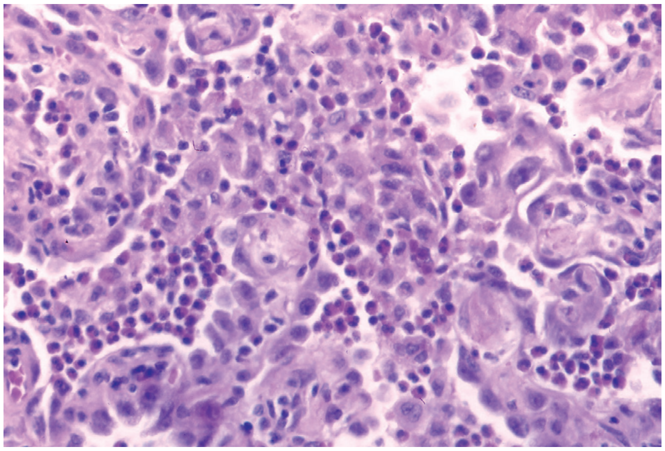

FIG 41.4 **Histology of Chronic Eosinophilic Pneumonia.** Lung biopsy specimen from a patient with chronic eosinophilic pneumonia demonstrates a confluent infiltrate with eosinophils filling alveoli together with large, multinucleate macrophages. Original magnification, ×200, hematoxylin and eosin stain.

Churg-Strauss Syndrome

Churg-Strauss syndrome (CSS), also termed *eosinophilic granulomatosis with polyangiitis* (EGPA), is a necrotizing vasculitis of medium and small caliber vessels (Chapter 58), which is characterized by airway obstruction and eosinophilia. The disease has an autoimmune nature, given the presence of circulating anti-myeloperoxidase and antineutrophil cytoplasmic antibodies (p-ANCA) as seen in 60–70% of affected individuals. Because CSS is seen in patients with a history of asthma and allergies and the prominent pathological feature is necrotizing vascular and tissue granulomas, the term “allergic granulomatosis and angiitis” is used synonymously. Inhaled or ingested antigens have been proposed as causative agents in susceptible individuals. Reports linking the syndrome with the LT inhibitors zafirlukast and montelukast in the setting of steroid withdrawal suggest that these agents may unmask preexisting CSS rather than directly causing the disorder. Similar observations have been made with omalizumab treatment. The vasculitis of CSS can affect the sinuses, the central and peripheral nervous systems, the GI tract, kidneys, and the heart. Treatment of CSS is based on the use of systemic steroids, which leads to disease resolution in the majority of patients. In severe steroid-resistant disease, cyclophosphamide and other immunosuppressants may be required.[21]

IMMUNOLOGICAL MECHANISMS OF ALLERGIC AIRWAY DISEASE

All patients with major allergic airway disease syndromes include patients who demonstrate evidence of allergic inflammation, with elevated blood and airway eosinophilia, elevated serum total and antigen-specific IgE levels, and positive skin prick tests. However, not all patients demonstrate all markers of allergic inflammation simultaneously, and some patients with apparent allergic disease express none of these markers. Specialized testing may also reveal predominant Th2 cytokine responses generated from peripheral blood mononuclear cells when stimulated with common allergens *in vitro* and the presence of Th2 cells, ILC2, eosinophils, and IgE-secreting B cells, and the secreted products of these cells, within affected sinus and airway tissues. As well as the conventional causes of Th2-mediated airway inflammatory

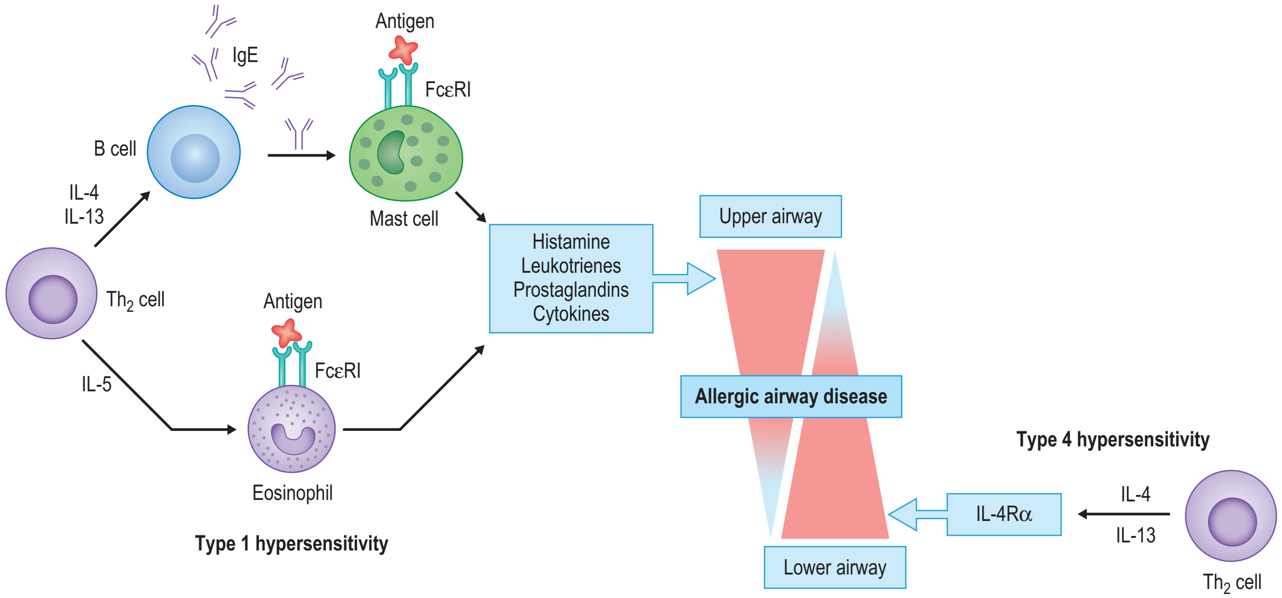

FIG 41.5 **Differential Importance of Allergic Immune Mechanisms According to Airway Level.** Type I hypersensitivity (left), mediated by immunoglobulin E (IgE)-primed mast cells and eosinophils, is ultimately driven indirectly by the cytokines secreted by T-helper 2 (Th2) cells. In contrast, type IV hypersensitivity (right) is mediated directly by Th2 cytokines, especially interleukin-4 (IL-4) and IL-13, acting through a similar receptor that includes IL-4Rα. Both immune mechanisms are important to the expression of allergic disease at all airway levels, but type I hypersensitivity predominates in the upper airway, whereas type IV hypersensitivity likely assumes a more important role in the lower airway.

responses, fungal and bacterial infections also serve as distinct causes of inflammation.

The major effector immune mechanisms of disease proposed by Gell and Coombs in the 1960s remain essential to understanding the pathogenesis of allergic airway diseases.[22] Although such mechanisms probably operate to some degree in all allergic diseases, their relative importance appears to vary, depending on whether the disease process predominantly affects the upper respiratory tract or the lower respiratory tract (Fig. 41.5).

KEY CONCEPTS

Immunopathogenesis of Allergic Airway Disease

- Gell and Coombs type 1 and type 4 hypersensitivity mechanisms contribute to disease expression, especially airway obstruction.
- Innate immune pathways involving thymic stromal lymphopoietin (TSLP), interleukin-25 (IL-25), and complement proteins critically contribute to the development of allergic airway inflammation.
- Environmental agents that are emerging as potentially important initiation factors for allergic airway inflammation include proteases, chitin, and endotoxin as derived from fungi, insects, and bacteria.
- Fungi and viruses are further emerging as potentially important infectious causes of allergic disease of the upper and lower airways.

Type I (Immediate) Hypersensitivity

This form of hypersensitivity involves the activation of basophils and mast cells that release histamine and other inflammatory mediators that drive the clinical features of the response. Antigen recognition is via IgE antibodies, which bind through their Fc portion to high affinity receptors (FcεRI) to arm effector cells. Th2 cells coordinate both the production of IgE antibodies and the activation and recruitment of allergic effector cells to the airway. Antigen-specific IgE bound to the surface of mast cells and basophils is cross-linked upon exposure to relevant antigens, causing cellular activation and release of preformed and newly formed mediators of inflammation, such as histamine, proteases, LTs, numerous cytokines, and other substances. IL-4, released primarily by Th2 cells, is an especially important regulator of type I hypersensitivity reactions, as it is required for B-cell maturation and IgE secretion.

There is evidence that IL-4 and IL-13 can mediate distinct effector phenotypes in airway and tissue macrophages and dendritic cells (DCs). Two major effector macrophage subtypes include conventionally activated (M1) macrophages that arise under the predominant influence of type I cytokines, especially IFN-γ, and alternatively activated macrophages (M2) that arise under the influence of IL-4 and IL-13 in the relative absence of IFN-γ. M2 macrophages express a distinct gene profile that includes high-level expression of arginase 1, Ym1, Fizz1 (RELM), and PD-L2. Current evidence suggests that M2 macrophages promote allergic responses and that redirecting them to the M1 phenotype might be therapeutically useful.[23]

The effect of mediator release in immediate hypersensitivity reactions is most dramatically illustrated by the clinical syndrome of anaphylaxis, in which patients may exhibit profound bronchoconstriction and dyspnea accompanied by the extravasation of vascular solutes and fluid into the interstitium, which produces diffuse edema, bronchoconstriction, and hypotension (Chapter 42). Type I hypersensitivity against inhaled allergens more commonly presents with symptoms of acute rhinitis.

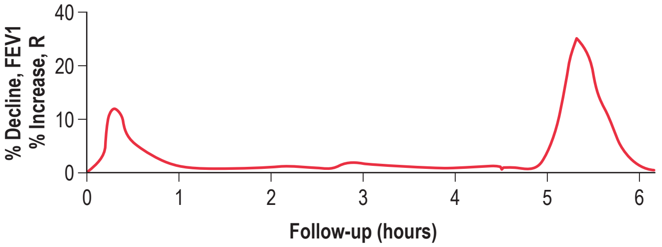

FIG 41.6 **Early-Phase and Late-Phase Airway Changes Following Allergen Challenge.** This schematic diagram depicts the two phases of bronchoconstriction typically seen after allergen inhalation in sensitized, asthmatic subjects. Within 20–30 minutes after allergen inhalation, the first (early) phase of bronchoconstriction as assessed by either a decline in forced expiratory volume per second (FEV_1) or increase in airway resistance (R) is seen. After quickly subsiding, approximately 4–6 hours (h) later, a second (late) phase of bronchoconstriction occurs.

Cell-Mediated Features of Immediate Hypersensitivity

Airway obstruction in allergen-sensitized asthma evolves over several hours after allergen exposure and is seen in two distinct phases. The early-phase response is marked by airway constriction that becomes maximal about 30 minutes after allergen exposure and is fully resolved after approximately 2 hours (Fig. 41.6). Approximately 50% of subjects with asthma who are tested will also develop a late-phase airway response in which airway obstruction again develops 4–6 hours after allergen exposure. Late-phase reactions are linked to the infiltration of the airways with Th2 cells and eosinophils, and the accompanying bronchoconstriction is less reversible with bronchodilating agents than the early-phase reactions.[24]

AHR is neurologically mediated through parasympathetic nerves, such as the vagus, and is fully reversible with bronchodilating agents that either interrupt muscarinic parasympathetic signaling directly (*e.g.*, ipratropium bromide) or activate receptors (*e.g.*, β_2-adrenergic) that antagonize muscarinic bronchoconstrictive pathways. Besides its formal demonstration in the clinical laboratory through bronchial provocation testing, AHR is recognized clinically as episodic bronchoconstriction that is reversed with bronchodilating agents. Late-phase responses after antigen challenge, therefore, represent a form of AHR and, in part, reveal the immunological nature of this ultimately neurological phenomenon.

More detailed analysis of the immunological mechanisms underlying AHR comes from experimental models of asthma. Studies from many species have demonstrated that AHR in the setting of allergic inflammation is critically dependent on Th2 cells and ILC2 that have specifically been recruited to the lung. Moreover, it is now clear that IL-13 is the major Th2 and ILC2 cytokine that mediates AHR by acting directly on constitutive airway cells, such as airway smooth muscle cells that express the IL-13 receptor. However, IL-13 does not directly induce bronchoconstriction. Bronchoconstriction in subjects with asthma, expressed as episodic bouts of dyspnea, is triggered by diverse exogenous factors in addition to allergens (*e.g.*, altered temperature and humidity, pungent odors, irritating aerosols) and endogenous stimuli (*e.g.*, extreme emotional states) with little apparent connection to immunological mechanisms. Thus rather than directly mediating airway obstruction, IL-13 establishes the basis for responding broadly to diverse agents with neurologically mediated bronchoconstriction. How IL-13 mediates these neurological changes is currently unknown.[11,25]

TABLE 41.2 **Chemoattractants Linked to the Recruitment of Allergic Inflammatory Cells**

Chemokine	Receptor
CCL1	CCR8
CCL11	CCR3
CCL17, CCL22	CCR4
CX_3CL1	CX_3CR1
Prostaglandin D2	CR T_H2
Leukotriene B4	BLT1

A second and more insidious form of airway obstruction is physical obstruction of the airways caused by mucus and fibrin clots that can accumulate in the airways as tenacious plugs, a phenomenon that is now termed plastic bronchitis.[26] IL-13, together with IL-9, is a trophic and differentiation factor for airway goblet cells and submucosal glands, which contribute to plastic bronchitis by promoting secretion of mucus by these cells. Airway obstruction caused by plastic bronchitis is not immediately reversible with bronchodilators or other pharmacological agents and is consequently the major cause of death, resulting from asphyxiation, in asthma.[27]

Finally, IL-4 and IL-13 further coordinate the recruitment and retention of allergic effector cells to airway epithelium and submucosa, an arrangement that facilitates rapid responses to inhaled allergens. Acting through a similar receptor, that includes the α chain of the IL-4 receptor (IL-4Rα), IL-4, and IL-13 signal on constitutive airway cells, such as airway epithelial cells, to induce secretion of a restricted repertoire of chemoattractants or chemotactic factors that promote the immigration of allergic cells expressing specific cognate receptors from the lung and airway microcirculation (Table 41.2).[28]

Contributing Immune Mechanisms in Allergic Airway Disease

In addition to its critical role in promoting IgE secretion, IL-4 is an important growth and differentiation factor for Th2 cells. Both IL-13 and IL-4 activate the transcription factor signal transducer and activator of transcription 6 (STAT6). In addition to these closely related cytokines, all components of the IL-4/IL-13 signaling pathway are required for expression of experimental allergic airway disease, especially AHR.

IL-5 also contributes to both immediate and cell-mediated hypersensitivity reactions through its role in promoting the growth and differentiation of eosinophils. Although widely viewed as pathogenic and contributing to the expression of allergic airway diseases, more recent studies indicate that eosinophils are important in tissue remodeling and in controlling allergic inflammation induced by pathogens, such as fungi.[29]

In addition to Th2 cells, mast cells, and eosinophils, innate lymphoid cells that include ILC2, natural killer (NK) cells (a type of ILC1), and $\gamma\delta$ T cells may also contribute to allergic disease expression through their ability to rapidly secrete Th2 and other cytokines.[25]

Numerous additional soluble mediators contribute to the expression of allergic disease. The complement system is especially important, and complement proteins C3a and C5a, the major proteolytically derived anaphylatoxins, are both essential for the expression and regulation of asthma in experimental systems. C3a signaling through the C3a receptor C3aR is required for robust Th2 responses, allergic inflammation, and AHR in response to airway allergen challenge. In contrast, C5a, which can signal through two receptors, C5aR and C5L2, appears to inhibit Th2 responses, perhaps acting as a physiological antagonist of the allergic disease-promoting activity of C3a.[30]

Lipid mediators of inflammation of importance to allergic airway disease include the LTs and prostaglandins (PGs). The cysteinyl leukotrienes (CysLTC4, -D4, and -E4) signal through at least two major receptors to mediate some of the same allergic disease features as IL-13, including airway inflammation and AHR. Full expression of experimental allergic disease, in fact, appears to require the concomitant expression of both IL-13 and the CysLTs. However, IL-13 appears to be the dominant allergic mediator, perhaps accounting, in part, for why LT antagonism alone is not as effective as inhaled steroids in asthma. Noncysteinyl LTs, such as LTB4, also contribute to the expression of allergic airway inflammation by controlling the recruitment of allergic effector cells, including Th2 cells.[31]

Similarly, PGD_2 is an important mediator of Th2 cell recruitment and allergic airway inflammation in rodent models, most likely acting cooperatively with LTB4 and chemokines. Most other PGs are thought to promote allergic airway disease, especially in aspirin-sensitive rhinitis and asthma. An important exception to this is PGE_2, which exhibits potent antiallergic activity. Other lipid mediators likely contributing to the expression of allergic inflammation and airway obstruction are the thromboxanes and lipoxins. Thromboxane A_2 is a potent proinflammatory lipid derived from platelets, whereas lipoxins have the opposite effect and are antiinflammatory.[32]

Environmental Factors and Allergic Disease Initiation

The earliest immunological events that initiate Th2 responses and the environmental factors that trigger them are incompletely understood. Currently, asthma and to a large extent RS and AR are believed to represent aberrant immunological responses to innocuous inhaled antigens. The very strong association between asthma and atopy supports this concept, with many allergens being relatively innocuous proteins derived from organisms that are not otherwise harmful or infectious, such as those from dust mites, cats, dogs, and plants. Atopy is further thought to represent a fundamental underlying condition that leads, in some cases, to overt allergic disease, but whether atopy represents primarily a genetically or an environmentally controlled condition remains unclear. Extensive analysis of allergens has revealed no consistent structural features, suggesting that physical properties are highly relevant to atopy and allergic disease expression.

A major exception to the intrinsically innocuous nature of allergens is, however, the role of filamentous fungi, such as *Aspergillus* spp., and other potentially infectious causes of allergic disease. Fungal sensitization is not different from sensitization to any other allergen ubiquitously present in human environments. However, fungi differ from all other allergen sources in that they are both ubiquitous and able to actively infect and grow within the respiratory tract.[33]

A fungal infectious basis for allergic disease is also suggested by *(i)* the high rate of isolation of filamentous fungi from the airways in CRS, especially AFRS, and ABPA; *(ii)* the universal presence of fungus-specific immunity in subjects with AFRS and ABPA; *(iii)* the efficacy of antifungal antibiotics when given to fungus-sensitized patients with asthma; and *(iv)* experimental validation that filamentous fungi are infectious for the mouse airway and readily produce allergic airway disease that is comparable with asthma. Moreover, fungal airway infection can induce atopy to innocuous bystander antigens, suggesting that fungal infection could underlie both atopy and respiratory tract allergic disease. However, not all patients with allergic airway disease demonstrate fungus-specific immunity; neither are antifungal agents effective in all such patients, especially those with CRS. Thus fungal airway infections may be etiologically relevant to only a subset of allergic disease patients.[33]

Respiratory viruses and particulate matter are also prominently linked to allergic airway disease. Approximately 70–80% of children and adults test positive for human rhinovirus (HRV) during acute disease exacerbations. Other respiratory viruses are likely to contribute to allergic disease pathogenesis, although the mechanisms remain obscure.[34] Particulate matter in the form of tobacco smoke, diesel exhaust particles, and other forms of smoke is strongly linked to asthma exacerbation and enhanced atopy, as is exposure to ozone (O_3). What links these various forms of air pollution to allergic disease may be the induction of oxidative stress, which ultimately leads to enhanced activation of nuclear factor kappa B (NF-κB), enhanced Th2 cytokine release, and increased allergic inflammation.[35]

Research from experimental systems has shed additional light on how allergens initiate allergic inflammation and disease. Although the structural features of allergens do not determine their allergic character, a common biochemical feature that is strongly associated with allergenicity is protease activity. Proteases, as single molecules, are as effective as any complex allergen or fungal infection in inducing allergic airway inflammation and AHR when administered to rodents or inhaled by humans. Household proteases are derived largely from fungi, suggesting again that airway infection caused by these organisms, which would result in *in situ* protease production, may be an important mechanism underlying allergic disease induction. Irritation of the airways through viral infection, ozone exposure, and other mechanisms further increases endogenous airway protease activity, especially through induction of thrombin activity.[36]

Analyses of diverse allergenic proteases suggest that they initiate a complex, airway epithelial-centered mechanism in which the epithelial cytokines TSLP, IL-33, and IL-25 are induced and lead to robust allergic responses. In part, this sequence is initiated by the action of exogenous and endogenous proteinases on the terminal coagulation protein fibrinogen, which is secreted by airway epithelial cells into the airway lumen. Cleavage of fibrinogen by proteases yields fibrinogen-cleaved products (FCPs) that signal through Toll-like receptor 4 (TLR4) to initiate both antifungal responses and innate allergic inflammation, including ILC2 responses.[37] Proteolytic activation of complement proteins (*e.g.,* C3) is also a crucial early event in the evolution of allergic airway disease.[30] Th2 responses arise, in part, through the action of proteases on pulmonary dendritic cells (Fig. 41.7).

NONALLERGIC RESPIRATORY TRACT INFLAMMATORY SYNDROMES

Although the majority of respiratory tract inflammatory disease is allergic, additional pulmonary immune-related disorders exist that are nonallergic and are responsible for considerable morbidity. The immunological mechanisms, etiological environmental factors, and therapies for these diseases are distinct from common

FIG 41.7 Mechanisms of Allergenic Protease-Dependent Induction of Allergic Airway Disease. Inhaled proteases or protease sources (*e.g.,* fungal spores) initiate a series of molecular events in discrete lung compartments and involving distinct cell types that induce predominant airway T-helper 2 (Th2) responses that coordinate both the allergic inflammation and physiological changes that typify allergic respiratory tract disease. Initial innate immune responses induced by proteases include induction of airway chemokines that favor recruitment of allergic effector cells including Th2 cells (1). Likely airway cellular targets of proteinases include basophils, epithelial cells, smooth muscle cells, and macrophages (2). Activation of these cells by cleavage of cell surface receptors, such as PAR2 and CD23, potentially leads to activation of these cells to produce proallergic cytokines, such as thymic stromal lymphopoietin (TSLP), interleukin-33 (IL-33), and IL-25 that promote Th2 responses. Allergenic proteinases also likely act on soluble substrates, such as complement, especially C3 to generate C3a, the ligand for the C3aR, and fibrinogen, creating fibrinogen cleaved products (FCPs) that signal through Toll-like receptor 4 (TLR4) to coordinate antifungal immunity and promote Th2 responses. CD25 is another immune receptor present on T cells that can be cleaved by proteinases, potentially to favor Th2 cytokine secretion. Finally, proteinases act directly on antigen-presenting cells, such as dendritic cells (DCs), through an unknown mechanism in secondary lymphoid organs, such as lymph nodes, to promote their maturation in a manner that favors Th2 cell differentiation from naïve precursor (ThP) T cells (3). (Modified from Porter PC, Yang T, Luong A, et al. Proteinases as molecular adjuvants in allergic airway disease. Biochim Biophys Acta 2011;1810:1059–65.)

allergic disorders and hence warrant consideration in the differential diagnosis of airway inflammatory disorders. Two of the most important nonallergic airway obstructive immune disorders are hypersensitivity pneumonitis and chronic obstructive pulmonary disease.

Hypersensitivity Pneumonitis

Hypersensitivity pneumonitis (HP) is a non–IgE-mediated inflammatory lung disease that results from recurrent exposure to a wide variety of inhaled antigenic aerosols containing organic and possibly infectious matter. Pulmonary involvement is typically diffuse and consists predominantly of mononuclear inflammation of the terminal bronchioles, interstitium, and alveoli, with little involvement of the larger airways. Although the term “extrinsic allergic alveolitis” is commonly used for this disorder, low-grade eosinophilia is only seen in 1–3% of BAL specimens and is not a consistent or characteristic feature of disease. Over time, this pattern of inflammation leads to destruction of alveoli and to irreversible pulmonary fibrosis that may ultimately be fatal.

The etiology of HP is usually idiopathic, but many cases can be traced to exposure to organic aerosols that contain thermophilic bacteria (*e.g., Saccharopolyspora rectivirgula*), filamentous fungi (*e.g., Aspergillus* spp.), animal proteins and fecal matter (*e.g.,* pigeon breeder’s disease), and industrial chemicals, such as isocyanates. Symptoms, including chest tightness, chest pain, dyspnea, and fever, appear 4–6 hours after exposure. Cessation of exposure to the provoking antigen may prevent progression to chronic, irreversible disease. Other than oxygen therapy in the setting of profound hypoxemia, there is no defined medical therapy for HP; in particular, there is no role for glucocorticosteroids.

The immunopathogenesis of HP is complex and not well understood. During the acute presentation, the histological picture is an immune complex–mediated interstitial injury with a predominant neutrophilic infiltrate. Subsequently, the disease evolves into predominant mononuclear inflammatory infiltrates consisting of lymphocytes, plasma cells, and foamy macrophages, followed by granuloma formation. In advanced disease, the inflammatory infiltrates are replaced by fibrosis.

Acutely, HP is thought to be initiated by an immune-complex mediated hypersensitivity (type III) with *in situ* immune complex deposition in the lung interstitium as a result of interaction of the inhaled antigen and preexisting IgG antibodies in the alveolar spaces. Complement activation occurs and most likely contributes to the alveolitis and neutrophilia. However, many people with precipitating antibodies to putative HP antigens (precipitins) do not develop actual parenchymal or symptomatic disease. Therefore it is believed type IV, delayed-type hypersensitivity reactions involving Th1 and possibly Th17 cells also contribute to disease expression.[38]

Chronic Obstructive Pulmonary Disease

The disorder most frequently confused with asthma is chronic obstructive pulmonary disease (COPD), which encompasses chronic bronchitis with or without emphysema. COPD is currently the fourth leading cause of death in the world but is expected to reach third place by 2020. The most common cause of COPD is active tobacco smoking, but chronic exposure to coal dust, biomass fuels, second-hand smoke, and chronic respiratory infections have been linked to COPD in nonsmokers. Because not all smokers develop COPD, disease initiation is thought to reflect interaction of genetic susceptibility and environmental factors. Development of early-onset emphysema in highly susceptible smokers is sometimes caused by undetected mutations in the α_1 antitrypsin (*A1AT*) gene locus (*e.g.,* ZZ, MZ, MS). However, in the vast majority of individuals, the genetic factors responsible for increased susceptibility to emphysema remain unknown. Indeed, several large studies have shown that although multiple genes contribute to increased risk of emphysema, each individual gene shows only a modest and independent effect.[39]

In addition to cough and sputum production, COPD often presents clinically with insidious onset of dyspnea and progressive and persistent exercise limitation, with minimal reversibility of airway obstruction. Epidemiological studies have shown that lung cancer risk is strongly related to radiographic emphysema, independent of air flow obstruction. In contrast, nonsmoking patients with asthma have no greater risk of lung cancer than the general nonsmoking population.

The Global Initiative for Chronic Obstructive Lung Disease (GOLD) has in the past decade promoted the use of a fixed FEV_1/forced vital capacity (FVC) ratio of <70% to diagnose COPD. This latter guideline is now widely used to classify smokers with and without COPD, but it excludes up to 20% of smokers with emphysema who have normal lung function, and it underdiagnoses and overdiagnoses COPD in young and old smokers, respectively. Recognizing different COPD phenotypes based on lung function, symptom severity, and exacerbation frequency, smokers are categorized into one of four stages: (A) fewer symptoms, low risk; (B) more symptoms, low risk; (C) fewer symptoms, high risk; (D) more symptoms, high risk. Those in groups C and D are thought to benefit from inhaled corticosteroids in addition to bronchodilators.[40]

Smokers with emphysema have enlarged alveoli that contain increased numbers of macrophages containing nano-sized elemental carbon black (nCB). The key property underlying the initiation of destructive lung inflammation with nCB inhalation appears to be its chemical characteristics, namely, its insolubility and small particle size that activate the inflammasome pathway and promote differentiation of lung Th1 and Th17 cells. nCB can be readily detected in lung phagocytic cells (*e.g.,* DCs and macrophages) by using Raman spectroscopy and electron microscopy (Fig. 41.8).[41]

The treatment of emphysema is largely supportive, comprising bronchodilators and cholinergic antagonists, which suppress mucus production, and inhaled or systemic glucocorticosteroids,

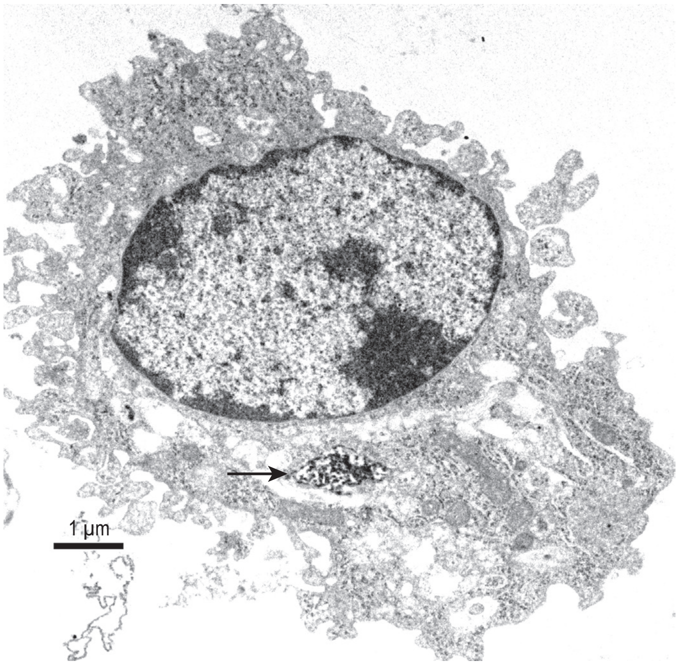

FIG 41.8 Nanoparticulate Carbon Black (nCB) Accumulation Within an Alveolar Macrophage. Electron micrograph of an alveolar macrophage isolated from the peripheral lung of a cigarette smoker with emphysema. Arrow points to a vacuole containing nCB.

https://archive.org/details/namdhari

which suppress inflammation. Additional therapies for moderate to severe disease include theophylline and the phosphodiesterase inhibitor roflumilast. During exacerbations of COPD, which become increasingly frequent with advancing disease and are often caused by bacterial and viral infections, tailored use of antibiotics is frequently helpful. For severe disease with resting hypoxemia, continuous nasal oxygen can both extend life and relieve dyspnea. Surgical interventions, such as lung volume reduction surgery and lung transplantation, are reserved for advanced disease.

The immunological basis of COPD differs markedly from asthma: smoking-related lung inflammation appears to be the fundamental underlying cause of both airway obstruction and lung destruction (Fig. 41.9). In contrast to asthma, where Th2 cells and other allergic effector cells are involved, the major immune effector cells in COPD are Th1 and Th17 cells. Together with macrophages and neutrophils, these innate and adaptive immune cells coordinate lung destruction in COPD by enhancing production of matrix metalloproteinases (MMPs) and other enzymes that degrade elastin (elastases), including MMP2, MMP9, MMP12, and neutrophil elastase (NE). The activity of most of these enzymes is controlled by endogenous inhibitors, such as tissue inhibitors of metalloproteinases (TIMPs) and A1AT, the principal antagonist of elastases. Cigarette smoke exposure is sufficient to enhance elastase secretion from macrophages and neutrophils and to reduce the activity of elastase inhibitors. In addition to elastin, MMP12 specifically inhibits A1AT, leading to unopposed NE activity. These biochemical events are critically important to the expression of emphysema because elastin is an important MMP that is partly responsible for both the structural integrity of the lung and its stretchiness. In genetically susceptible individuals, elastin becomes the antigenic target of pathological Th1 and Th17 cells. Emphysema, therefore, is the clinical expression of the autoimmune-based loss of lung integrity resulting from enhanced expression of antielastin immunity that promotes secretion of elastases.[42]

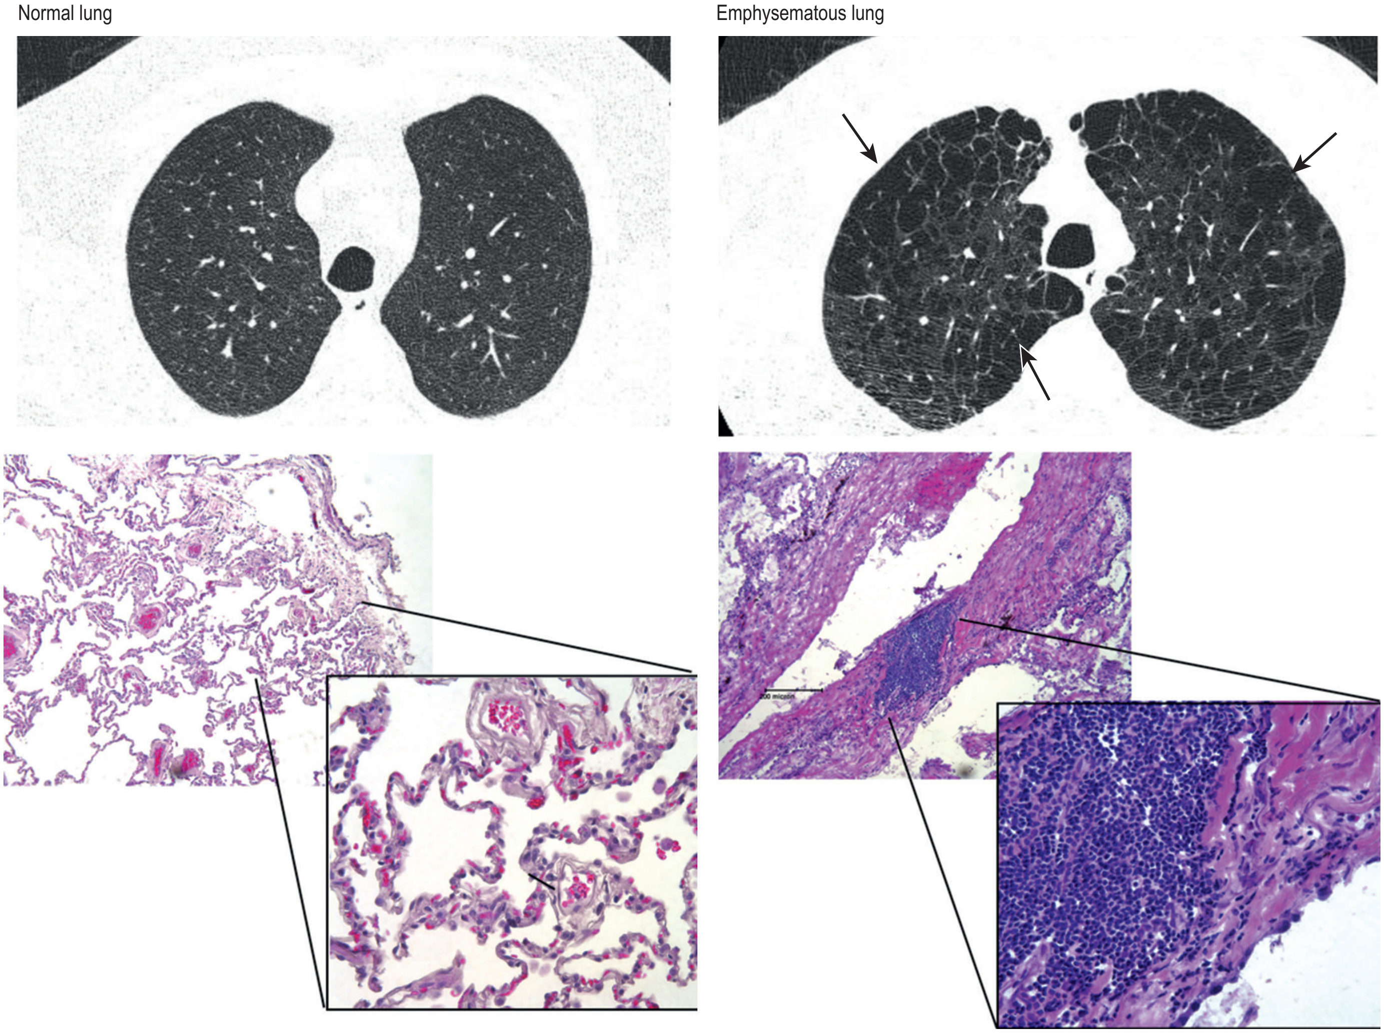

FIG 41.9 **Lung Parenchymal Destruction in Smokers With Chronic Obstructive Pulmonary Disease (COPD) and Emphysema.** Representative computed tomography (CT) images show lungs of a smoker without (A) and with (B) emphysema; arrows point to low attenuation dark black areas devoid of lung tissue (emphysematous regions) within the diseased lung. Lower panels show representative low- and high-magnification histology images from human lung in each case including the focal collection of inflammatory mononuclear cells in emphysematous lung.

NOVEL PATHWAYS TO THERAPY IN INFLAMMATORY AIRWAY DISEASE

Intensive research conducted over the past several decades has markedly improved our understanding of the immune and environmental basis of allergic and nonallergic airway diseases. Currently available therapies for these diseases have, however, failed to match this level of sophistication. It is now clear that allergic disease is immunologically complex and likely to involve multiple hypersensitivity mechanisms operating in parallel. Recent studies also show that factors other than allergens likely critically influence the airway immune response to inhaled antigens and particulate matter. These adjuvant factors include cell wall products of bacteria and fungi, such as lipopolysaccharide (LPS); secreted factors, such as proteases; and endogenous factors from cells damaged by exposure to allergens and smoke. There is increasing evidence that asthma and RS may be linked to respiratory tract infections involving viruses, especially HRV, and filamentous fungi. Future therapies are, therefore, likely to focus on both endogenous factors that coordinate allergic inflammation (*e.g.*, cytokines) and etiological environmental factors (*e.g.*, proteases, fungi, and nCB).

Once thought of as primarily a physical barrier, the respiratory epithelium is now recognized to actively coordinate immunity to allergens and other environmental challenges. Through release of IL-33, IL-25 and/or TSLP, respiratory epithelial cells can initiate and coordinate the innate and adaptive type 2 immune response (see Fig. 41.7). In addition, respiratory epithelial cells produce several chemokines in response to environmental triggers, recruiting DCs, ILC2s, basophils, eosinophils, and mast cell progenitors.[43] Several of the triggers listed above and also trauma to airway cells can activate the release of these type 2 cytokines and chemokines.

The prototypical epithelial cell cytokines, IL-25, IL-33, and TSLP, share many overlapping functions supporting a local type 2 inflammatory response despite having unique receptors. As expected, many of the type 2 cells, including eosinophils, DCs, ILCs, and mast cells, express receptors to all three cytokines. Despite functional overlap, these cytokines also possess unique functions. For example, IL-33 and IL-25 activate different types of ILCs, with IL-33 primarily activating ILC2 and IL-25 preferentially stimulating a novel population of type 2 innate cells. TSLP is associated more with activation of the adaptive type 2 inflammatory response via DCs. Also, TSLP uniquely supports the hematopoiesis of basophils. Together, these epithelial cell derived cytokines orchestrate a robust innate and adaptive type 2 inflammatory response as well as initiating necessary repairs to the epithelial cell barrier.[43]

ON THE HORIZON

- Increasingly sophisticated clinical trials focused on interrupting key immunological pathways (*i.e.*, interleukin [IL]-4, IL-13 signaling pathway) in allergic disease
- Focused research on the importance of infectious pathogens, microbial adjuvant moieties, and air pollution in allergic disease initiation and perpetuation
- Development of immunologically based diagnostic and prognostic strategies for asthma, chronic sinusitis, and possibly other allergic airway disorders
- Clinical studies that reassess the validity of the predominant use of general immunosuppression in comparison to targeted antiinflammatory approaches

Recent clinical studies have confirmed the importance of Th2- and ILC-derived cytokines, including IL-5 and IL-13, to the pathogenesis of human allergic disease. The anti–IL-5 antibody mepolizumab was recently approved by the US Food and Drug Administration (FDA) for use in eosinophilic asthma; anti–IL-13 (lebrikizumab) and anti–IL-4/IL-13 receptor (dupilumab) antibodies are likely to be approved for similar indications.

In addition to defining disease populations that are most likely to benefit from them, a major challenge with all biological agents is their prohibitive cost. Development of small, relatively easily manufactured molecules that antagonize disease-related pathways is, in many ways, a more attractive approach with lower pharmaceutical costs. Small molecule agonists of peroxisome proliferator activated receptor-γ (PPAR-γ) are currently approved for use in diabetes mellitus (pioglitazone, rosiglitazone) in the United States, but they are also outstanding antagonists of Th17 cells and can reverse experimental emphysema.[44] Thus PPAR-γ agonists are excellent candidates for future clinical trials in emphysema. Small molecule antagonists of IL-4/IL-13 signaling that target STAT6 have also been discovered and are potentially suitable for clinical trial and development.[45]

In future studies, it will be essential to clarify the role of chronic infections caused by viruses, bacteria, and fungi in asthma and RS. Although recent studies firmly implicate a central infectious role for fungi in CRSwNP and asthma, it is a major challenge to design clinical trials that unequivocally demonstrate whether antifungal antibiotics are useful in asthma and CRS.[9]

The central role played by proteases and the proteolytic activation of complement (*e.g.*, C3) and coagulation-related inflammatory pathways (*e.g.*, fibrinogen) in allergic diseases suggest that antiproteases might be effective in the management of these conditions. Broad-spectrum antiproteases are effective in attenuating human and experimental asthma and are, thus, suitable for further therapeutic development.[37] The major obstacles with these agents are discovering molecules with sufficiently broad spectrum to inhibit the proteases of the many fungi now linked to human allergic disease and overcoming potential safety issues related to their anticoagulant and immunosuppressive properties.

MULTIPLE-CHOICE QUESTIONS

1. What epithelial cell–derived cytokine contributes to the pathophysiology of chronic rhinosinusitis (CRS) by serving as the primary driver of mucus production?
   A. Thymic stromal lymphopoietin (TSLP) via activation of dendritic cells
   B. Chemokine ligand 11 (CXCL11) via its chemotactic role for activated T cells
   C. Interleukin-33 (IL-33) via activation of innate lymphoid cells
   D. IL-25 via increased expression of IL-4

2. Which of the following characteristics MOST clearly distinguishes chronic obstructive pulmonary disease/emphysema from asthma?
   A. Airway obstruction
   B. Lymphocytic inflammation
   C. Disease exacerbations leading to disabling dyspnea
   D. Autoimmune responses against elastin
   E. Disease is linked to environmental exposures

3. Which of the following factors is most clearly implicated as an etiological environmental factor in human emphysema?
   A. Molds (fungi)
   B. Nanoparticulate carbon black (nCB)
   C. *Haemophilus influenzae*
   D. Endotoxin (lipopolysaccharide; LPS)
   E. Radon gas

4. Future therapies for asthma could target which of the following?
   A. IL-13
   B. IL-4 receptor
   C. IL-5
   D. Fungi
   E. All of the above

42

Urticaria, Angioedema, and Anaphylaxis

Clive E.H. Grattan, Elena Borzova

Urticaria is a common skin disorder that can lead to severe impairment in quality of life. Recently, there has been substantial progress in our knowledge and understanding of the pathophysiology of the condition, offering new diagnostic and treatment approaches for many patients.

DEFINITION

Urticaria is characterized by itchy wheals, angioedema, or both.[1] Urticarial lesions resulting from localized edema of the upper dermis are called *wheals* (Fig. 42.1), whereas pronounced swelling of deeper dermal layers and subcutaneous and submucosal tissues is known as *angioedema* (Fig. 42.2).

KEY CONCEPTS

Definition of Urticaria

- Urticaria is an illness characterized by wheals, angioedema, or both.
- Wheals are superficial swellings of the dermis of skin: they are pale and itchy with surrounding redness when they appear and then become pink before fading.
- Angioedema is a deep swelling below the skin or mucosa that usually lasts longer than wheals and may be painful rather than itchy.
- Wheals may occur with or without angioedema in urticaria.
- Acute urticaria lasts <6 weeks. It is common and often caused by viral infections. Urticaria caused by drugs and foods falls in this category, but the diagnosis is usually clear from the history.
- Chronic urticaria lasts ≥6 weeks with continuous disease activity. A cause may not be found. Urticaria occurring intermittently over a period of >6 weeks can be defined as episodic.
- When angioedema occurs without wheals, C1 esterase inhibitor deficiency should be excluded.

EPIDEMIOLOGY

Urticaria is common, and up to 25% of the general population experience some form of urticaria at least once over their lifetime, whereas the lifetime prevalence of chronic urticaria (CU) is 0.1–3% of the general population.[2] Acute urticaria mainly affects young adults and has an obvious female preponderance,[2] whereas CU is more common in adults, affecting mainly middle-aged women, and is uncommon in children and adolescents.[3] By definition, acute urticaria resolves within 6 weeks, whereas CU may last for years. Rarely, CU may last >10 years. However, CU is almost always a self-limiting disorder, resolving spontaneously within 6 months of onset in 50% of patients.[3]

GENETICS

Although there is no indication of mendelian inheritance, the frequency of chronic spontaneous urticaria (CSU) is higher in first-degree relatives of patients.[4] A link between CU and human leukocyte antigen (HLA)-DRB1*04 (DR4) and its associated allele, -DQB1*0302 (DQ8), was found in British patients with CSU with evidence of functional autoantibodies compared with a control population.[5] Strong associations with HLA-DRB1*1302 and DQB1*0609 alleles were found in aspirin-induced urticaria in Korean patients.[6]

CLINICAL PATTERNS

Urticaria is classified by the duration of continuous activity into acute (<6 weeks), chronic (≥6 weeks), or episodic, where short episodes occur repeatedly over a period, with short or long intervals. It may be spontaneous, inducible, or both. Inducible urticarias may be triggered by mechanical, thermal, or other stimuli. The differential diagnosis of urticaria includes urticarial vasculitis, hereditary angioedema (HAE), and autoinflammatory syndromes presenting with urticarial rash.

ETIOPATHOGENESIS AND ETIOLOGICAL CLASSIFICATION

Although many aspects of the pathophysiology of urticaria remain unclear, our understanding has advanced considerably over the last two decades, allowing for an etiological classification (Table 42.1).

Mast Cell–Dependent Mechanisms

Skin mast cells are key players in the pathogenesis of urticaria. They are predominantly located around the small blood vessels and lymphatic vessels as well as around or within peripheral nerves. The population density of mast cells is greatest at distal body areas, including the face, hands, and feet.[7] There is conflicting evidence as to whether the number of cutaneous mast cells is increased in patients with urticaria, but it is accepted that these cells release mediators more readily compared with normal cells.

Human skin mast cells contain preformed mediators in their granules, including histamine, proteases (tryptase, chymase), and heparin. They express many membrane receptors, including high-affinity immunoglobulin E (IgE) and low-affinity IgG receptors. Unlike mast cells elsewhere (*e.g.*, lung and gastrointestinal [GI] tract), skin mast cells possess complement C5a

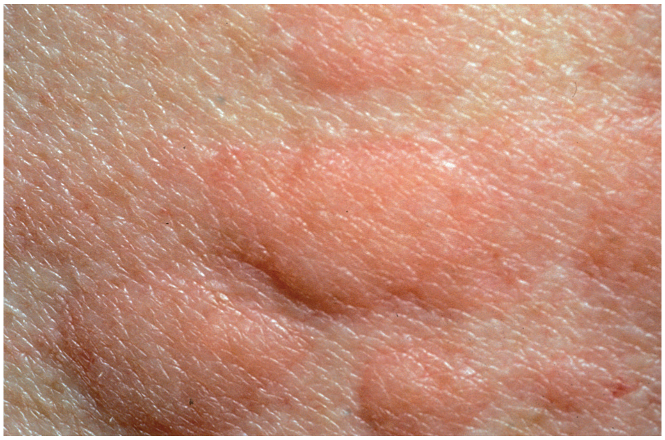

FIG 42.1 Spontaneous wheals in severe spontaneous urticaria showing superficial pink swellings with pale edematous centers.

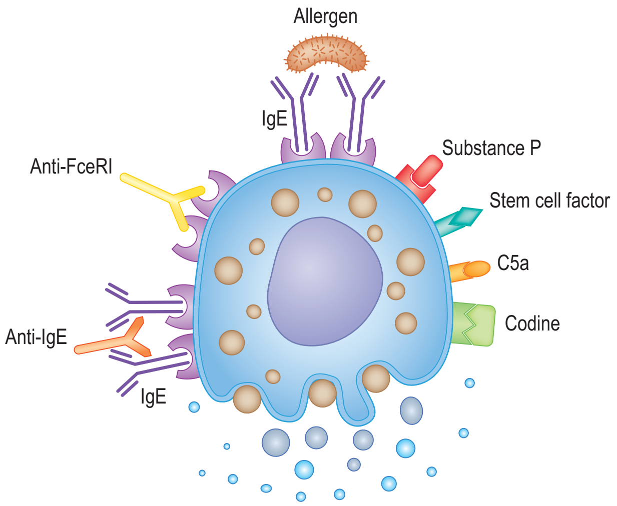

FIG 42.3 Schematic representation of a mast cell or basophil illustrating activation of the immunoglobulin E (IgE) receptor by cross-linking with immunological stimuli (allergen/specific IgE binding, anti-IgE, or anti-FcεRI autoantibodies) or independent activation by nonimmunological stimuli (substance P, stem cell factor, codeine, or C5a) leading to degranulation.

receptors and activation sites for neuropeptides and basic secretagogues.

Skin mast cell activation is central to the pathophysiology of CU. Mast cells can be activated by a variety of immunological and nonimmunological triggers (Fig. 42.3). Immunological and nonimmunological pathways of mast-cell activation are characterized by distinct patterns of mediator release. Immunological activation of mast cells is triggered by cross-linking of high-affinity IgE receptors (FcεRI) by antigen bound to antigen-specific IgE, by anti-FcεRIα, or by anti-IgE antibodies. Histamine release peaks at 5–10 minutes, followed by *de novo* synthesis of lipid-derived mediators (leukotriene C4 [LTC4] and prostaglandin D_2 [PGD_2]) and cytokines.[8] In contrast, nonimmunological stimulation of mast cells by neuropeptides, opiates, or C5a leads to rapid release of histamine within 15–20 seconds, without generation of eicosanoids and cytokines. Moreover, prolonged and subthreshold immunological stimulation may result in a state of receptor desensitization. For example, desensitization of FcεRI may lead to basophil hyporesponsiveness to anti-IgE in autoimmune CSU.[9] However, desensitization of receptors by immunological stimulation does not affect nonimmunological release.

Allergic Urticaria

The classic example of immunological mast-cell activation via high-affinity IgE receptors is IgE-mediated urticaria (often termed *allergic urticaria*). Cross-linking of receptor-bound IgE leads to the release of diverse preformed mediators and newly synthesized lipid mediators and cytokines, resulting in the early- and late-phase IgE-mediated allergic inflammatory responses.

IgE-mediated mast-cell activation can present as acute urticaria in those individuals previously sensitized to exogenous allergens. IgE to autoantibodies are implicated in chronic wheeling. Examples include some food- and drug-induced urticarias and latex-induced contact urticaria. Allergic urticaria to inhaled allergens (*e.g.*, latex, animal epithelia) is often accompanied by respiratory symptoms. Generalized allergic urticaria may progress to anaphylaxis. Allergic urticaria resolves rapidly on withdrawal of allergen exposure and recurs with each reexposure to the allergen or cross-reactive agents.

Autoimmune Urticaria

Functional autoantibodies directed against the extracellular α-chain of FcεRI on dermal mast cells or basophils or, less frequently, against receptor-bound IgE have been demonstrated in 25–50% of adult and pediatric patients with CSU.[9,10] The pathophysiology of autoimmune CU involves cross-linking of high-affinity IgE receptors by autoantibodies leading to degranulation of mast cells and basophils. There is good evidence that activation of

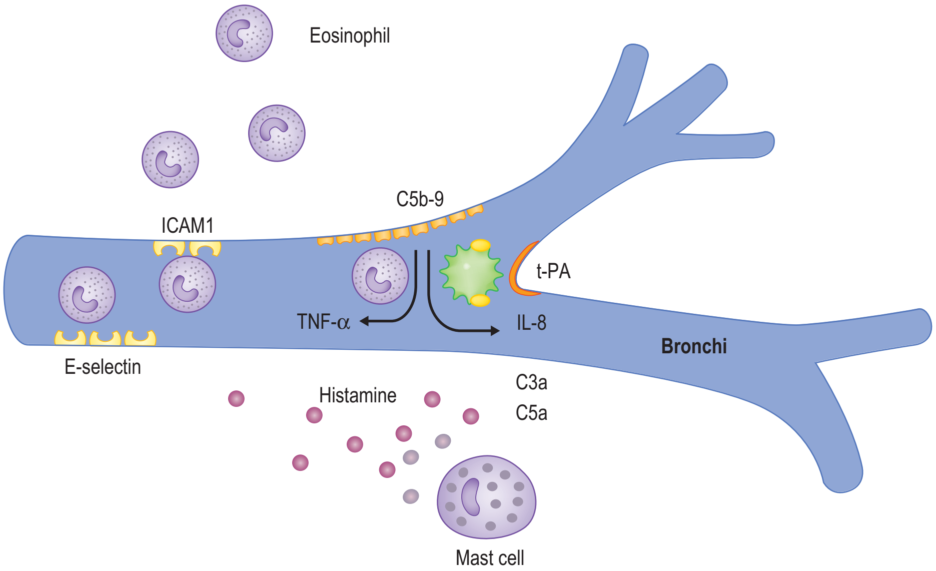

FIG 42.4 Immune Complex-Mediated Urticaria Initiated by Lodging of Antigenic Complexes in Small Blood Vessels Followed by C3a and C5a Generation. This results in mast cell degranulation and cytokine upregulation of adhesion molecules (intercellular adhesion molecule [ICAM]-1, E-selectin) by tumor necrosis factor-α (TNF-α) and interleukin-8 (IL-8), which leads to tissue recruitment of neutrophils and eosinophils and activation of tissue plasminogen activator (t-PA).

cutaneous mast cells by IgG derived from CSU sera *in vitro* is dependent on C5a, but not all histamine-releasing IgG derived from CSU sera are complement dependent on basophil assays. Most functional autoantibodies are IgG1 or IgG3, which are known to fix complement. By contrast, nonfunctional anti-FcεRI autoantibodies demonstrated by Western blot or enzyme-linked immunosorbent assay (ELISA) in other autoimmune diseases (including systemic lupus erythematosus [SLE] and bullous pemphigoid) are generally from the noncomplement-fixing subclasses IgG2 and IgG4.[10]

The low-affinity IgE receptor FcεRII/CD23 expressed on B lymphocytes and eosinophils may be another target antigen for an autoimmune response in CSU. Anti-CD23 antibodies have been detected in patients with CSU.[11] The interaction between anti-CD23 antibodies and CD23 on eosinophils may induce release of major basic protein 1 (MBP-1), a potent IgE-independent histamine-releasing agent, resulting in activation of mast cells and basophils.

Immune Complex–Mediated Urticarial Rash

Mast-cell activation can result from binding of circulating immune complexes to FcγRIII, expressed on mast cells. In addition, circulating immune complexes can activate complement, leading to C3a and C5a anaphylatoxin formation. Urticarial rash caused by immune complexes can occur acutely in serum sickness–like reactions, transfusion reactions, some drug-induced urticarias, and urticaria associated with infectious or autoimmune diseases. Immune complex–mediated urticarial rashes usually develop 1–3 weeks after initial exposure to the antigen and disappear several weeks after antigen discontinuation. Chronic wheeling mediated by immune-complex damage and associated with a histological evidence of leukocytoclastic vasculitis is known as *urticarial vasculitis* (see below). In this condition, urticaria can be associated with systemic symptoms, such as fever, arthritis, or nephritis, especially the uncommon hypocomplementemic variant (hypocomplementemic urticarial vasculitis syndrome [HUVS]). Damage to postcapillary venules results from the deposition of immune complexes in the vessel wall. Immune complexes are formed on exposure to external (drug or infections) or internal (collagen-like region of C1q) antigens. Complement activation via the classical pathway leads to neutrophil chemotaxis through cytokine expression and adhesion molecule activation (Fig. 42.4). Proteolytic enzymes released from neutrophils damage vessel walls, leading to wheal formation and red blood cell (RBC) extravasation.

Nonimmunological Mast-Cell Activation

Skin mast cells can be activated nonimmunologically by many agents, including neuropeptides (substance P, neuropeptide Y, vasoactive intestinal peptide, or somatostatin), calcitonin gene-related protein, compound 48/80, and natural polyamines. Drugs (*e.g.*, opiates, muscle relaxants, radiocontrast media, polymyxin B) can also cause dose-dependent nonimmunological urticaria by activating membrane-associated G-coupled proteins. A classic clinical example is codeine-induced acute urticaria.

Mast-Cell and Basophil Releasability in Urticaria

In patients with CSU, dermal mast cells show a decreased activation threshold. Although CSU basophils are often hyporesponsive to anti-IgE, they are paradoxically hyperresponsive to an as yet unidentified factor in normal human serum.[10]

Skin Response to Mast-Cell Activation in Chronic Urticaria

Despite the existence of different pathways for mast-cell activation, the end result is degranulation with release or secretion of mediators. Histamine is crucial for the development of cutaneous manifestations of urticaria and is found in high concentrations in tissue fluid of wheals. It causes localized redness resulting from vasodilatation, wheal formation from increased vascular permeability leading to plasma leakage, and a surrounding axon reflex-mediated flare-up. Histamine is also the main mediator of itch in urticaria. However, histamine-induced wheals are short-lived in contrast to urticarial lesions that may persist up to 24 hours, implying that other proinflammatory mediators and/or cellular infiltrates contribute to CSU pathogenesis.

Mast Cell–Independent Mechanisms of Urticaria

Pseudoallergy (Intolerance)

Pseudoallergy, or nonallergic hypersensitivity, mimics immediate-type allergic reactions clinically without evidence of underlying immunological mechanisms.[12] The most common triggers of pseudoallergic reactions are aspirin and other nonsteroidal antiinflammatory drugs (NSAIDs), as well as some food ingredients and additives, such as salicylates, benzoates, and tartrazine. These reactions do not involve IgE sensitization and can, therefore, occur on first exposure. Pseudoallergic reactions are dose-dependent and usually occur with chemically nonrelated substances. The diagnosis is difficult because skin tests and serology are uninformative. Diagnosis of nonallergic hypersensitivity is based on a distinctive clinical pattern, time course, clinical signs, and response to elimination of the cause. In the appropriate clinical context, pseudoallergy can be confirmed with oral challenge tests.

NSAIDs

Aspirin and other NSAIDs inhibit constitutive cyclooxygenase (COX-1) and inducible cyclooxygenase (COX-2), thereby diverting arachidonic acid metabolism toward the 5-lipoxygenase pathway in some cell types, notably eosinophils. This modulation of arachidonic acid metabolism results in overproduction of cysteinyl-leukotrienes LTC4, -D4, and -E4, leading to vasodilatation and edema. Furthermore, reduction of PGE_2 formation by COX inhibition has two further effects that promote urticaria: first, by reducing inhibition of cysteinyl leukotriene production and second, by reducing an inhibitory effect on immunologically-mediated mast-cell degranulation (Fig. 42.5). Cross-sensitivity occurs with other nonselective NSAIDs in susceptible individuals, depending on their pharmacologic potency for COX inhibition but not their chemical structure.

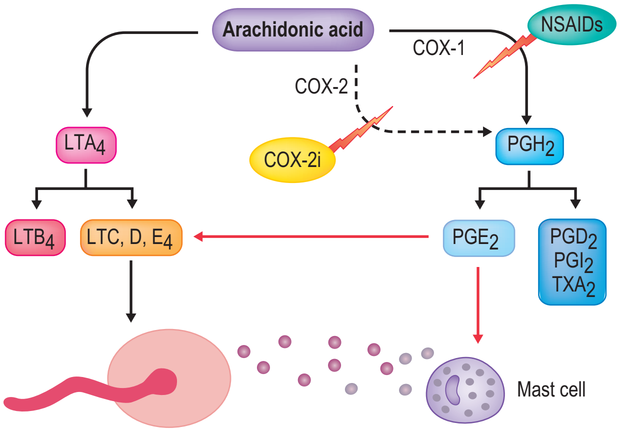

FIG 42.5 Arachidonic acid pathways illustrating potential diversion from prostaglandin synthesis to cysteinyl leukotrienes (LTC4, -D4, -E4) by blocking cyclooxygenase (COX), leading to increased vasopermeability. Reduction of prostaglandin E_2 also reduces its direct inhibitory effect on leukotriene production and on immunological mast cell degranulation.

Aspirin and NSAIDs can trigger acute urticaria as well as causing flare-ups of preexisting chronic spontaneous (but not physical) urticaria. Aspirin-induced exacerbations have been reported in 20–40% of patients with CSU.[13] In some patients, aspirin can act as a cofactor in food- or exercise-induced anaphylaxis.

Urticaria can develop from a few minutes to 24 hours after aspirin ingestion but usually within 1–2 hours. Angioedema of the lips and tongue, impaired swallowing, and laryngeal edema develop occasionally. Aspirin-induced skin symptoms usually subside 24–48 hours after discontinuing the drug. However, severe exacerbations of CSU caused by aspirin and other NSAIDs can last from several days to several weeks after aspirin intake.[13]

There are no skin tests or reliable *in vitro* diagnostic techniques for patients with aspirin-induced urticaria, and the diagnosis can only be established by challenge tests. Patients should avoid aspirin and other NSAIDs, but COX-2 inhibitors (coxibs) are usually well tolerated and can probably be used safely.

Food-Induced Pseudoallergic Reactions in CSU

Pseudoallergic food reactions appear to be important in some patients with CSU. Pseudoallergic food triggers include natural salicylates in fruit and vegetables and artificial food additives in processed foods, such as benzoates and tartrazine. Low-molecular-weight aromatic compounds in tomatoes, white wine, and herbs have also been implicated.[14] Clinically, exacerbations of CSU resulting from dietary pseudoallergens gradually subside within 10–14 days on an exclusion diet; in contrast, in 1–3 days in acute allergic urticaria. One study showed increased gastroduodenal and intestinal permeability in patients with CU. Responders to elimination of pseudoallergens in their diet demonstrated normalization of mucosal permeability and skin symptoms. Although the underlying mechanisms for pseudoallergic reactions in CU remain unproven, an impaired gastroduodenal barrier function may be a contributory factor.[14]

Kinin-Mediated Angioedema

The mediator of angioedema resulting from hereditary and acquired C1 esterase inhibitor (C1-INH) deficiency and angiotensin-converting enzyme inhibitor (ACEI)–induced angioedema is bradykinin rather than histamine or leukotrienes. There is currently no evidence that kinins are involved in other types of urticaria or angioedema. Bradykinergic angioedema is not considered a type of urticaria.

CLINICAL CLASSIFICATION

CU may be spontaneous, inducible, or both.

Spontaneous Urticaria

Spontaneous urticaria is the most common presentation. The term “spontaneous” makes no assumption about etiology, which may include autoimmunity, allergy, pseudoallergy, or infection. Those cases for which a cause cannot be ascertained with reasonable confidence are called *idiopathic*. In practice, this is the majority of patients. Spontaneous urticaria can be further classified by duration and frequency of attacks into acute, chronic, and episodic urticaria.

Acute Spontaneous Urticaria

Acute urticaria is defined as continuous disease lasting <6 weeks. Individuals with an atopic predisposition are at higher risk of acute urticaria; atopic diseases are found in about half the patients with acute urticaria.[3] Most acute urticaria resolves spontaneously within 3 weeks, but in 10% of patients, it may progress to CSU.

Infections are the most common identifiable cause of acute urticaria, with some cases resulting from foods or drugs. A specific cause of acute urticaria will not be found in about 50% of patients. Foods are the most common cause of acute urticaria in young children but are rarely responsible for acute urticaria in adults. In infancy, cow's milk allergy may cause acute allergic urticaria. Drug-induced urticaria is the most common presentation of drug hypersensitivity, accounting for a quarter of all adverse drug reactions, with penicillin and NSAIDs being the most common causes of allergic and nonallergic drug-induced urticaria, respectively. Drug-induced urticaria is more likely in older adults, perhaps reflecting polypharmacy and age-related pharmacokinetic changes, and in patients with human immunodeficiency virus (HIV) infection and those with renal or liver diseases.

Chronic Spontaneous Urticaria

CSU is characterized by daily or almost daily itchy wheals on skin, with or without angioedema, for ≥6 weeks. In 30–50% of patients, CSU is caused by functional autoantibodies against the α chain of the high-affinity IgE receptor or against IgE itself.[10] Functional abnormalities of basophils have also been described. However, in 50% of patients, the etiopathophysiology of the disease remains unknown and appears to be endogenous. Whatever the primary cause, CSU appears to be aggravated by a variety of exogenous exposures, including acute infections (most commonly viral upper respiratory tract infections), NSAIDs, dietary pseudoallergens, menses in women, tiredness, and stress. The presence of these factors probably explains why the clinical course is often erratic and unpredictable.

CSU affects women twice as often as men. There is a common link between CSU and thyroid autoimmunity (present in about 14–25% of CU cases) as well as other autoimmune diseases, including Graves disease, vitiligo, and insulin-dependent diabetes. CSU is often associated with inducible urticaria (*e.g.,* delayed-pressure urticaria [DPU]). Around 50% of patients present with both wheals and angioedema. CU can have a continuous or a relapsing course. CU of all types, including CSU, can cause serious disability in patients, including loss of sleep and energy, social isolation, altered emotional reactions, and difficulties in aspects of daily living similar in degree to patients with severe ischemic heart disease.

Episodic Spontaneous Urticaria

The cause of episodic urticaria often remains unknown, but the possibility of an allergic or pseudoallergic cause needs to be considered.

Inducible Urticarias

Inducible urticarias are common, accounting for 25% of all cases of CU. These include physical urticarias, such as symptomatic dermographism, cold and heat urticarias, DPU, solar urticaria, and vibratory angioedema, in which symptoms are triggered reproducibly by an external mechanical or thermal/ultraviolet stimulus. The inducible group now also includes cholinergic, adrenergic, aquagenic, and contact urticarias, in which the eliciting stimuli for mast-cell degranulation are defined by a nonphysical exposure. Inducible urticarias can coexist with CSU (*e.g.,* DPU or dermographism), and more than one inducible urticaria can occur in the same patient (*e.g.,* dermographic and cholinergic urticarias), which may lead to difficulty in diagnosis. With the exception of DPU, inducible urticarias develop rapidly after exposure to the relevant trigger and fade within an hour.[2]

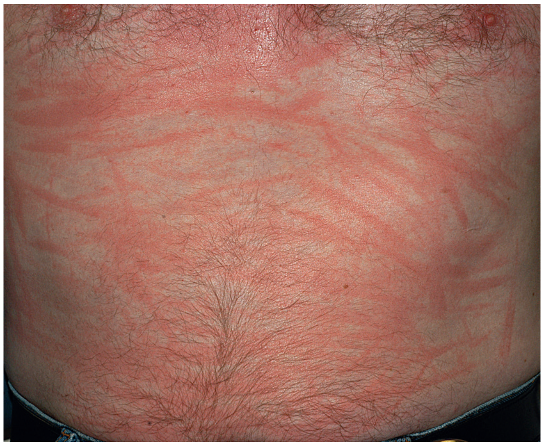

FIG 42.6 Extensive induced dermographic whealing on the chest of a patient as a result of scratching.

The pathogenesis of inducible urticarias is unclear except in the case of allergic contact urticaria, which is caused by mucocutaneous exposure to an allergen to which the individual has already developed IgE sensitization. A diagnosis of physical urticaria is confirmed if the symptoms can be reproduced by challenge testing with the suspected stimulus.[15] Challenge testing can be used for monitoring threshold changes during treatment. In general, treatment of inducible urticarias involves avoidance of known triggers and taking antihistamines. Sometimes tolerance can be induced for cold and solar urticarias.

Mechanical Urticaria

Symptomatic Dermographism

Dermographism is the most common physical urticaria, mainly affecting young people. Typical red, itchy, linear wheals are evoked within minutes of stroking, friction, rubbing, or scratching the skin (Fig. 42.6). Overheating, stress, and anxiety usually aggravate symptoms. The diagnosis of dermographism is confirmed by stroking the skin with a blunt firm object or a calibrated instrument, such as a dermographometer (HTZ, Croydon, U.K.) or FricTest (Moxie, Berlin, Germany), usually on the upper back.

Delayed Pressure Urticaria

Isolated DPU occurs in just 2% of all patients with urticaria, but DPU coexists with CSU in up to 40% of patients. DPU is the most debilitating of the physical urticarias and is triggered by sustained local pressure (*e.g.,* wearing tight shoes, carrying heavy bags, long walks, sitting or leaning against firm objects, climbing ladders, jogging, driving, or clapping hands). Deep and painful swellings, clinically resembling angioedema, develop 30 minutes to 12 hours after pressure, and may be associated with flu-like symptoms, fever, arthralgia, and fatigue. The most frequently affected sites are hands, soles, buttocks, shoulders, and areas under straps and belts. DPU lesions last 12–48 hours and are usually painful rather than itchy, especially on the hands and feet. Laboratory investigation reveals transitory leukocytosis and elevated erythrocyte sedimentation rate (ESR). Hanging a heavy weight suspended on a narrow band over the forearm or thigh for 15 minutes may be used as a challenge test, but more reliable results can be obtained with a dermographometer applied at 100 g/mm^2 for 70 seconds. The reaction should be assessed after 2–6 hours. DPU is difficult to treat because it responds poorly to antihistamines.

Vibratory Angioedema

Vibratory angioedema is rare. Familial cases have been described. Local swelling develops several minutes to 6 hours after using vibrating machinery, lawn mowing, applauding, and jogging, for instance. Systemic symptoms may occur (headache, chest tightness, diffuse flare). Placing the elbow or hand on a laboratory vortex for 5–15 minutes is a useful challenge test. Avoidance of the trigger is the only helpful treatment strategy.

Thermal or Ultraviolet-Induced Urticaria

Cold Urticaria

Cold urticaria accounts for about 3% of physical urticarias.[16] It occurs in both children and adults and is more common in cold climates, in women, and in atopic patients. The majority of cases are primary with no identifiable cause, but some cases are secondary to internal disease. Clinical manifestations can be local or generalized. Mucosal involvement may develop after drinking cold beverages. Systemic symptoms may be respiratory (laryngeal angioedema, tongue or pharyngeal swelling, wheezing), vascular (hypotension, tachycardia), GI (hyperacidity, nausea, diarrhea), or neurological (disorientation, headache). Cold-induced urticaria can be evoked by low ambient temperature, contact with cold objects, food or beverages, or immersion in cold water. Wheals develop during the cold exposure or, more commonly, on rewarming. The severity of cold urticaria depends on the intensity and duration of the cold stimulus. Cold urticaria is potentially life threatening, with a risk of anaphylaxis and death on exposure of large skin areas to cold, for example, jumping into cold water and hypothermia in neurosurgical and cardiothoracic operations. Familial cold urticaria is caused by mutations in the cold-induced autoinflammatory syndrome (*NLRP-3*) gene and is no longer classified as an inducible urticaria.

In 1–5% of patients, cold urticaria is secondary to cryoproteins (mainly cryoglobulins). These can be associated with infections (hepatitis C, infectious mononucleosis, syphilis, *Mycoplasma* infection), autoimmune diseases, and lymphoreticular malignancy (Waldenström macroglobulinemia, myeloma), but these are rare. Cold urticaria can precede these diseases by several years. Secondary cold urticaria can also be drug-related (penicillin, oral contraceptives, ACEIs).

The diagnosis of cold urticaria is confirmed by an ice cube challenge or TempTest (Moxie, Berlin, Germany). Some atypical cold-induced urticarias have negative results in the ice cube test.

The clinical workup in cold urticaria includes measurement of cryoproteins. Patients should be cautious about bathing or swimming in cold water and consuming cold food or drinks. Antihistamine treatment is often helpful but does not prevent anaphylaxis caused by swimming in cold water. In severe cold urticaria, tolerance induction may be attempted: this involves depletion of mast-cell histamine by repeated cold exposure.

Heat Urticaria

Heat-induced urticaria is very rare. It is induced by local heating of the skin at 38–44°C. Challenge test is done by application of hot water in a tube or beaker at up to 44°C for 4–5 minutes or TempTest (Moxie, Berlin, Germany). Symptoms develop several minutes after exposure. Management of heat-induced urticaria presents some difficulty, as antihistamines are only of limited value.

Solar Urticaria

Solar urticaria affects about 1% of all patients with urticaria and has a slight female predominance. It can be associated with erythropoietic porphyria. Wheals are caused by electromagnetic wavelengths ranging from 290 to 760 nm (ultraviolet B [UVB], UVA, and visible spectrum). It develops within minutes or hours after sun exposure and fades within 24 hours. Lesions are usually confined to sun-exposed skin, although they can also develop under clothing. The severity of solar urticaria depends on the wavelength, intensity, and duration of irradiation. Short exposures induce flare and pruritus, whereas longer exposures cause whealing. In patients sensitive to the visible spectrum, reactions may occur through window glass.

Solar urticaria is diagnosed by phototesting. Patients are advised to use creams with a high sun protection factor (SPF), protective clothing, and protective window shields and to limit the time spent outdoors.

Other Patterns of Inducible Urticaria

Cholinergic Urticaria

Cholinergic urticaria is the second most common physical urticaria and occurs mainly in adolescents, young adults, and patients with atopy. Cholinergic urticaria usually follows a rise in core temperature resulting from physical exercise, fever, or external passive heat (hot bath, shower, sauna) but may also be provoked by emotional stress and spicy food. The characteristic lesions are highly pruritic pinpoint pale wheals of 1–3 mm surrounded by a red flare. The wheals may occur anywhere except the soles and palms. Lesions usually begin on the trunk and the neck, extending outward to the face and limbs. As lesions progress, confluent areas of whealing and redness may develop. Severely affected patients may develop angioedema and even anaphylaxis. Most patients with mild disease do not seek medical help. The rash is triggered by activation of cholinergic sympathetic innervation of sweat glands, but the mechanism of activation remains unclear. Decreased blood protease inhibitor levels have been reported, and this is the rationale for using anabolic steroids to treat occasional severely affected individuals who are unresponsive to other measures. The prognosis is reasonably favorable, with spontaneous resolution within 8 years in most patients. However, 30% of patients are affected for over 10 years.

Cholinergic urticaria can be confirmed by reproducing the rash with exercise or passive heating in a hot bath at up to 42°C. Treatment is primarily with antihistamines, but beta-blockers, danazol, ketotifen, and montelukast have also been used. The condition may be refractory for up to 24 hours, and this may enable patients to prevent attacks by taking daily exercise.

Aquagenic Urticaria

Aquagenic urticaria is very rare. It occurs in women more often than in men and is triggered by water contact but not after drinking water. Scattered small papular wheals, similar to cholinergic urticaria but with a larger flare, appear within 10–20 minutes of water contact and resolve in 30–60 minutes. Diagnosis is made by using a challenge test in which a wet compress at body temperature is applied for up to 10 minutes on whichever part of the body is usually affected. Associations with HIV and hepatitis B infection have been described.

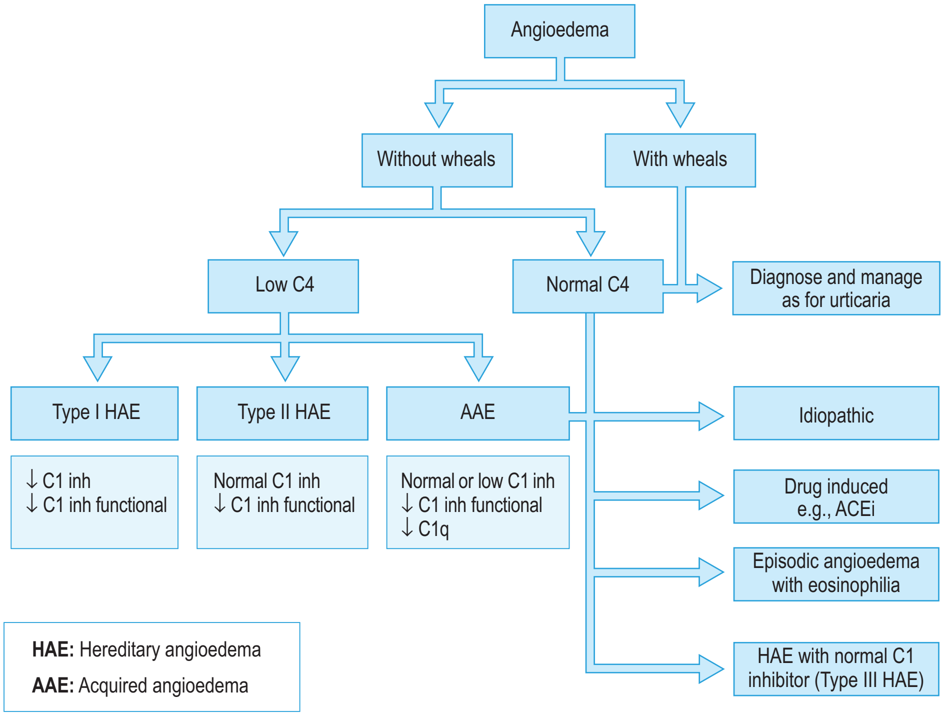

FIG 42.7 Diagnostic pathway for the differential diagnosis of angioedema.

Contact Urticaria

Contact urticaria occurs locally after skin or mucosal contact with the eliciting agent.[2,3] Reactions usually develop within a few minutes and resolve over 2 hours, although delayed-contact urticaria can occur with a latent period up to 48 hours. Contact urticaria can be caused by many organic and inorganic stimuli, such as latex, animal danders and secretions, foods, plants, topical drugs, and cosmetics.

Allergic contact urticaria occurs mainly in atopic subjects. IgE sensitization can occur through skin, mucous membranes, and the respiratory or GI tract. Foods are the most common cause. In ≈15% of patients, contact with the allergen may induce anaphylaxis. The severity of contact reactions depends on many factors (area of exposure, duration of contact, amount and concentration of substance, patient reactivity, comorbidity, and concomitant treatment).

Nonallergic contact urticaria is commoner than allergic contact urticaria and is usually caused by low-molecular-weight chemicals. Contact urticaria to benzoic acid in food is thought to involve generation of eicosanoids because it can be blocked by NSAIDs, but for other substances (*e.g.,* polyvinylchloride, polyethylene glycol), the mechanism remains unknown. Nonallergic contact urticaria may occur on first exposure and may depend on dose and concentration of the chemical.

DIFFERENTIAL DIAGNOSIS OF URTICARIA

Urticarial Vasculitis

Urticarial vasculitis is characterized clinically by CU and histologically by leukocytoclastic vasculitis on lesional skin biopsy.[17] It is important to differentiate urticarial vasculitis from CSU in terms of prognosis, approach to diagnostic evaluation, and therapy.

Angioedema Without Wheals

Angioedema occurs in nearly half the patients with CSU; in these patients, the disease tends to be more severe and more difficult to treat. Angioedema without wheals occurs in about 10% of patients with CSU but needs specific investigation because it may be caused by C1 inhibitor deficiency or drugs, although many cases remain unexplained (Fig. 42.7).

Angioedema Caused by C1 Inhibitor Deficiency

The diagnosis and clinical presentation of hereditary and acquired C1-INH deficiency are covered in Chapter 21.

Angioedema With Normal C1 Inhibitor

Histaminergic angioedema (without wheals)

Idiopathic. Idiopathic angioedema is diagnosed when no cause can be established. It is generally self-limiting but may follow a prolonged course. Treatment of idiopathic angioedema is as for spontaneous urticaria. Antihistamines are the mainstay of therapy; corticosteroids (prednisolone 30–40 mg/day) are useful for up to 3 days to cover more severe episodes, and epinephrine is lifesaving in laryngeal angioedema. Tranexamic acid can help in idiopathic angioedema without wheals, but it is usually ineffective when angioedema occurs with urticarial wheals.

Drug-induced. Angioedema without wheals occasionally occurs with NSAIDs, usually within several hours of intake.

Bradykininergic angioedema

Hereditary. Some kindreds have been described with a dominant pattern of angioedema inheritance, mainly in women, in whom a gain-of-function (GOF) mutation of the contact pathway of coagulation in *F12* has been found in about 20% of affected families. This used to be called type III HAE, but the term *hereditary angioedema with normal C1 inhibitor* is now preferred.[18]

Drug-induced. Angioedema develops in 0.1–2% of patients on ACEIs. Of these, up to 40% of patients present with life-threatening angioedema of the upper airway. It is thought to result from inhibition of kininase II, which breaks down bradykinin, as well as converting angiotensin I to angiotensin II in the renin–aldosterone pathway. It usually presents with episodic and unpredictable swellings of the head and neck, especially of the tongue and oropharynx. Although, in most cases, angioedema develops within the first week of treatment with ACEIs, symptom onset may occur after several years on treatment. Management involves discontinuation of ACEI therapy. Angioedema often recurs on reexposure to ACEIs. ACEIs may also precipitate angioedema in patients with angioedema from other causes, including C1-INH deficiency. Rare instances of angioedema have been reported with angiotensin II receptor antagonists.

Autoinflammatory Syndromes Presenting With Urticarial Rash

Acquired

Schnitzler syndrome. Schnitzler syndrome is a rare form of CU with intermittent fever, bone pain, high ESR, and monoclonal IgM, or, very rarely, IgG gammopathy.[19] Clinically, patients present with nonpruritic or mildly pruritic CU, mainly affecting the trunk and limbs. The wheals are resistant to antihistamines, and angioedema is rare. Fever bouts may exceed 40°C, sometimes with chills and nocturnal sweating. Patients often suffer from bone pains, mainly in the pelvis or tibias, arthralgia, and sometimes full-blown arthritis. Lymphadenopathy, hepatomegaly, and splenomegaly may be present.

Kappa light-chain monoclonal IgM and, less commonly, IgG paraproteins are found on serum electrophoresis. The ESR is persistently elevated at 60–100 mm/hour, with leukocytosis, elevated platelet count, and anemia. Skin histology shows neutrophilic urticaria with a tendency to localize around appendages in most cases; monoclonal IgM is deposited in the epidermis around the keratinocytes and along basement membranes on direct immunofluorescence. Bone examination may demonstrate hyperostosis on radiography and hyperfixation on bone technetium scanning. Bone marrow examination shows normal results in most patients, but nonspecific lymphocytic, plasmocytic, or polyclonal infiltration is present in about 20%.

The pathophysiology of Schnitzler syndrome is still unclear, and the severity of urticarial rash does not depend on the paraprotein level. Evidence of activation of interleukin-1 (IL-1), increased IL-6, and granulocyte macrophage–colony-stimulating factor (GM-CSF) and anecdotal reports of complete clinical responses to the IL-1 receptor antagonist anakinra suggest that cytokines play a leading role in its pathogenesis. The prognosis is generally good. However, long-term follow-up is recommended because patients may develop B-cell lymphomas 10–20 years after its onset.

Hereditary (Cryopyrin-Associated) Periodic Syndromes

Several hereditary autoinflammatory urticarial syndromes show mutations of the *NLRP-3* gene on chromosome 1q44. *NLRP-3* encodes a protein called cryopyrin, which is involved in apoptosis and inflammation. These rare autosomal dominant disorders include familial cold autoinflammatory syndrome (FCAS), Muckle-Wells syndrome (MWS), and chronic infantile neurological, cutaneous and articular (CINCA) syndrome, now grouped under the inclusive term *cryopyrin-associated autoinflammatory syndrome* (CAPS).[20]

DIFFERENTIAL DIAGNOSIS

Several dermatoses may present with urticarial lesions, including erythema multiforme minor, bullous pemphigoid, and dermatitis herpetiformis. These dermatoses can nearly always be distinguished clinically from urticaria on the basis of their polymorphic pattern, prolonged duration of individual lesions, lack of daily fluctuation, development of vesicles or blisters, and resistance to conventional therapy for urticaria. Very occasionally, skin biopsy, with or without indirect immunofluorescence, may be required to make the distinction.

Papular urticaria is an urticarial reaction to insect bites in sensitized individuals. The lesions are fixed rather than fluctuating, may take days or weeks to resolve fully, and may leave pigmentation or scars. Bites often occur asymmetrically in groups or lines. Although histamine is involved in the initial pruritic lesions, oral antihistamines are usually unhelpful, and potent topical steroids may be required to speed up natural resolution.

WORKUP IN PATIENTS WITH URTICARIA

Evaluation of patients with urticaria requires a detailed history and a physical examination.[21] The history is particularly important in patients with urticaria and should include a thorough inquiry for all potential causes of the disorders, possible precipitating and aggravating factors, the timing of onset and duration of individual wheals, associated symptoms as well as travel history, recent infection, occupational exposure, food and drug intake, and comorbidity. Patients may be asked to keep a diary of attacks and complete weekly urticarial activity scores for CSU.[1] The duration of individual lesions can be very helpful in distinguishing the different clinical patterns of urticaria.

Physical examination should focus on skin lesion morphology and careful systemic evaluation for underlying disease or comorbidities. If the patient is symptom-free at the time of evaluation, photographs taken when the symptoms occur are helpful. The approximate duration of individual lesions can be assessed by outlining a particular lesion with a pen and observing it for a day. The appearance and distribution of skin lesions may suggest a diagnosis (*e.g.,* the pinpoint lesions with a large flare in cholinergic urticaria or lesions on sun-exposed areas in solar urticaria).

Further evaluation of patients with urticaria is guided by the patient history and clinical pattern of disease. However, it must be remembered that there can be more than one cause for urticaria and that different clinical subtypes of urticaria can coexist in one patient.

CLINICAL PEARLS

Diagnosis of Clinical Patterns of Urticaria

- The duration of individual wheals can help define the pattern of urticaria.
- Wheals lasting ≤1 hour are usually triggered by a physical stimulus.
- Localized wheals lasting up to 2 hours may be caused by skin or mucosal contact with an allergen or a nonimmunological exposure.
- Wheals that take 1–24 hours to fade are usually a presentation of chronic spontaneous urticaria.
- Wheals lasting >24 hours may be caused by delayed pressure urticaria or urticarial vasculitis.

Workup in Acute Urticaria

When allergens are suspected as the cause there should be a close temporal relationship to the time of exposure, usually starting within minutes, a history of previous exposure causing sensitization and prompt resolution on allergy withdrawal. IgE sensitization can be assessed by skin prick testing or fluoroenzymatic immunoassay (FEIA) (also known as serum specific IgE testing).

Workup in Physical Urticarias

When physical urticaria is suspected, appropriate challenge testing should be performed to confirm the diagnosis.[22] Generally, there is no need for further investigation, except for cold urticaria, where blood cryoglobulins should be assayed.

Workup in Chronic and Episodic Spontaneous Urticarias

No laboratory workup is recommended for patients with mild CSU that is easily controlled by antihistamines, unless the history points to an underlying disease. Studies have shown that random laboratory testing very rarely yields evidence of unsuspected internal diseases as a cause of CSU, and this should therefore be discouraged.[21]

Screening laboratory evaluation can be considered in patients with poor response to first-line antihistamine treatment. A complete blood count (CBC) with differential, ESR, thyroid-stimulating hormone (TSH), thyroid antibodies, liver function tests, and urinalysis will exclude most diseases associated with urticaria.

Other evaluations should be guided by abnormal findings in the history and physical examination in patients with CSU. Additional tests may include stool examination for ova and parasites and *Helicobacter pylori*, antinuclear antibody titer, hepatitis viral screening, and skin prick or blood tests for specific IgE in episodic urticaria if there is a story of intermittent allergen exposure. Tests for immediate hypersensitivities should not be undertaken in chronic continuous urticaria unless there are compelling reasons for doing so. Rarely, CSU can be caused by a specific food additive, which should be confirmed by dietary exclusion and double-blind, placebo-controlled oral challenge.

The Diagnosis of Autoimmune Chronic Urticaria

The diagnosis of autoimmune CU is not straightforward and involves *in vivo* and *in vitro* approaches. Autologous serum skin testing (ASST) is a simple and useful screening method for autoreactivity in patients with CU. For skin testing, 0.05 mL of the patient's own serum should be injected intradermally into clinically uninvolved forearm skin, together with an equal volume of saline as a negative control. Histamine 10 mg/mL can be used as a positive control. The reaction is considered positive if the serum skin test forms a pink wheal at least 1.5 mm greater than the negative control at 30 minutes. The test is 80% specific and 70% sensitive for autoimmune CU as defined by a positive basophil histamine release assay.[23]

The current diagnostic gold standard in autoimmune CSU is a functional release assay using whole sera on healthy donor basophils or mast cells, but these only give indirect evidence of functional autoantibodies. Being technically difficult, these assays are mainly confined to research centers. Nonfunctional immunoassays (Western blot, ELISA) based on binding of autoantibodies to relevant antigens (FcεRIα or IgE) do not correlate well with the results of functional assays.[10]

MANAGEMENT OF URTICARIA

Finding effective treatment for urticaria can be challenging. Treatment should be tailored to the clinical pattern, duration, and severity of the urticaria. Management should include nonpharmacological measures and drug therapy with a stepwise approach.[1]

THERAPEUTIC PRINCIPLES

Management of Urticaria

- Eliminate infectious, drug, or food causes.
- Minimize nonspecific aggravators, including heat, stress, alcohol, nonsteroidal antiinflammatory drugs, and pressure.
- Regular oral H1 antihistamines are the first line of therapy for all spontaneous and inducible urticarias.
- Second-line treatments, including short courses of oral corticosteroids, may be necessary for specific clinical situations.
- Immunosuppressive therapies should be reserved for patients with severe autoimmune urticaria or steroid-dependent urticaria that has not responded to other first- and second-line measures.
- Omalizumab (monoclonal anti-IgE) is effective in chronic spontaneous urticaria refractory to H1 antihistamines

General Measures

Causes, triggers, and aggravating factors should be avoided or minimized, whenever possible. Patients with CSU should minimize exposure to nonspecific aggravating factors, such overheating, wearing tight clothes and shoes, stress, alcohol, dietary pseudoallergens, and some drugs. NSAIDs aggravate up to 30% of patients with CSU and are usually avoided. This does not apply to the physical urticarias, in particular DPU, where NSAIDs may be used as treatment. ACEIs are contraindicated in angioedema without wheals that may be mediated by kinins but not in other patterns of urticaria. Although it is often recommended that patients with CSU avoid codeine and penicillin, clinical experience suggests that this is not necessary. Cooling lotions and creams, such as 1% menthol in aqueous cream, may help relieve pruritus. Some patients with spontaneous but not inducible CU appear to respond to a low-pseudoallergen diet.[12] However, controlled clinical trials are lacking.

First-Line Therapy

Antihistamines are the cornerstone of treatment for all types of histaminergic urticaria. Second-generation antihistamines offer several advantages over classic H1 antihistamines, including lack of sedation and impairment of performance, longer duration of action, and absence of anticholinergic side effects. Meta-analysis indicates that antihistamines are effective in 40–90% of patients with CU. Second-generation antihistamines are inverse agonists of H1 receptors, which stabilize H1 receptors in the inactive conformation and are, therefore, most effective in CU when taken regularly for prophylaxis. The timing of antihistamine intake should be adjusted to suit the diurnal pattern of urticaria for each individual. Although the evidence base for combining H1 and H2 antihistamines is poor, this may be helpful. H2 antihistamines also suppress the dyspepsia that often accompanies severe urticaria.

Second-Line Therapy

It has become common practice to increase second-generation antihistamines above their licensed doses up to fourfold when CU does not respond because clinical experience and updosing studies show that this achieves better control in some patients. When urticaria does not respond to first-line measures, systemic corticosteroids are commonly used as short-term rescue therapy for acute urticaria or severe exacerbations of CU. Long-term treatment with oral corticosteroids is not recommended because of safety concerns. In corticosteroid-dependent patients, an alternate-day dosing schedule may be used, and steroid-sparing drugs should also be considered. A wide variety of medications have been reported to be of benefit for antihistamine-unresponsive urticaria when oral corticosteroids might otherwise have to be considered, but they are invariably used off-label, and controlled trials are usually lacking. Where possible, these should be targeted at specific subgroups of urticaria patients (*e.g.,* the LT receptor antagonist montelukast has been shown to be effective in aspirin-sensitive patients with CSU, and there is limited evidence for a trial of thyroxine in biochemically euthyroid patients with CSU who have thyroid autoimmunity).

Third-Line Therapy

The recent approval of omalizumab (anti-IgE) as add-on therapy for CSU not responding to antihistamines has transformed the management of severe disease in many patients. The recommended dose is 300 mg by monthly subcutaneous injection, although clinical experience indicates that lower (and occasionally higher) doses may be effective and the interval between treatments can be extended in good responders. Clinical experience suggests that when used off-label, it may also be effective for many patients with inducible urticarias. The mechanism of action is still not certain but probably involves reduction of high-affinity IgE receptors on mast cells and basophils as a consequence of a rapid fall in circulating free IgE and a later reduction in IgE bound to mast cells, resulting in a stabilizing effect. Experience to date suggests that omalizumab is often highly effective for control of urticaria symptoms (including itch) but probably does not modify the natural history of the illness.

Immunosuppressive therapy is mainly considered for autoimmune CSU. However, it may also benefit therapy-resistant CSU without evidence of circulating antibodies.

The best-studied immunosuppressive therapy is cyclosporine, shown to be effective initially at 4 mg/kg daily in patients with CSU. Patients must be monitored carefully for renal impairment and hypertension; treatment should normally be limited to 4 months. Cyclosporine is contraindicated in patients with previous malignant disease except nonmelanoma skin cancer. There is some evidence for efficacy of plasmapheresis and immunoglobulins in chronic autoimmune urticaria, although these are expensive options, and controlled clinical trials are needed. Methotrexate, mycophenolate mofetil, and azathioprine have also been used alone or with corticosteroids.[14]

MANAGEMENT OF HEREDITARY ANGIOEDEMA

The swellings of HAE are mediated by kinins rather than histamine, so the management of HAE is completely different from mast cell–dependent urticaria. The primary aim of therapy is to replace the missing functional C1 esterase inhibitor or stabilize the coagulation, fibrinolysis, complement, and kallikrein–kinin pathways. ACEIs should be avoided because ACE is a key enzyme involved in the breakdown of bradykinin. Angiotensin II receptor agonist (ARA 2) are probably safe alternatives. Exogenous estrogen (oral contraceptives and hormone replacement therapies) should be avoided in women, since it appears to activate kallikrein through activated factor XII. Lifestyle events that exacerbate HAE vary in their importance among individuals but may include local trauma (*e.g.,* dental extraction), stress, tiredness, and intercurrent infections, possibly including *Helicobacter pylori* infection. Attacks involving the extremities or abdomen are the most common. It is estimated that over their lives, up to 50% of patients will experience an attack of oropharyngeal swelling, with risk of asphyxiation, so treatment must be rapidly available for emergencies in all patients as well as as a preventive measure. The intention of treatment is to reduce or curtail the severity of a swelling and to reduce "downtime" if one occurs. Some patients with frequent peripheral swellings prefer to treat themselves symptomatically with analgesics and wait for spontaneous resolution over 3–4 days, rather than have specific treatment, since no treatment is completely without risk of adverse effects, and there are potential problems with cost and/or availability. The management of types I and II HAE is better defined than type III but follows similar principles.[24]

Treatment of the Acute Attack

The "gold standard" treatment for oropharyngeal or GI attacks in most countries (except the United States until recently) has been plasma-derived nanofiltered C1 esterase inhibitor (pd-C1-INH) concentrate given by intravenous infusion. It has proven to be effective and safe. The recommended dose is 20 units/kg body weight in adults and children, although smaller doses have been used in the past and may be effective. Up to 3 units of fresh frozen plasma (containing C1 inhibitor and its substrate, complement) may be given as an alternative in an emergency when pd-C1-INH is not available, but it will not have had the same stringent screening and production measures to eliminate the possibility of transmissible infection. Initial improvement in the swelling may be seen within 30–60 minutes, and time to clearance is usually in the order of 24 hours after pd-C1-INH. Self-administration can reduce the severity of attacks by allowing earliest treatment and should be encouraged. A recombinant C1-INH is licensed in Europe. Icatibant (a bradykinin 2 receptor antagonist) is also highly effective for acute episodes of HAE. Ecallantide (a kallikrein antagonist) is currently licensed in the United States but not in Europe. Both are given by subcutaneous injection, which provides an easier route for administration than intravenous infusion. Ecallantide should be given under medical supervision, since there is a small risk of allergic reactions. Icatibant is licensed for self-administration, which provides a potential advantage. There have been no head-to-head studies of pd-C1-INH, ecallantide, and icatibant, but experience suggests that the effectiveness of these products is comparable. It should be noted that antihistamines and steroids have no place in the management of HAE. Any improvement resulting from epinephrine's effects on vasopermeability will be transient, and there is no evidence that it changes the overall course of an attack.

Short-Term Prophylaxis

It has become common practice to give prophylactic treatment with pd-C1-INH before procedures involving local trauma to the oropharynx, including dental extraction and intubation for general anesthesia. The dose for prophylaxis may be less than that needed for treatment of an acute attack. Common practice is to give at least 500 units pd-C1-INH 1 hour before the procedure, with a further dose available in case a swelling develops. Other strategies include increasing the dose of prophylactic treatment with anabolic steroids (danazol or stanozolol) or plasmin inhibitors (tranexamic acid or ε-aminocaproic acid) for at least 48 hours before and after the procedure. Specific guidance on dosing for adults and children can be found elsewhere.

Long-Term Prophylaxis

Anabolic steroids are the mainstay of long-term prophylaxis in countries where they are licensed for use in the treatment of HAE. They increase the production of C1-INH by the liver in heterozygotes with a functioning allele. The dose should be titrated against the clinical response rather than blood levels of C1-INH to the lowest level that prevents or ameliorates the condition. Virilizing side effects can be problematic for women, and anabolic steroids are avoided in children because of concerns about growth retardation. Monitoring of liver function and lipid profiles should be undertaken periodically. Performing a liver ultrasound examination every 3 years to screen for development of hepatoma is usually recommended in patients on long-term prophylaxis. Plasmin inhibitors are generally less effective for prophylaxis compared with anabolic steroids but are preferred in children. pd-C1-INH infusions twice a week may be given as prophylaxis during pregnancy and in rare situations when alternative therapies are not appropriate.

Anaphylaxis

Anaphylaxis is a severe, life-threatening, systemic reaction of sudden onset and involves respiratory compromise, cardiovascular collapse, or both. Its clinical features and management have been summarized in international guidelines.[25-28]

Epidemiology of Anaphylaxis

Estimates of the incidence of anaphylaxis in the general population in Europe and the United States vary from 50 to 103 cases per 100 000 per annum.[29] Lifetime personal risk estimate for anaphylaxis in the general population is believed to be 0.05–2%.[30] The mortality rate in anaphylaxis is estimated to be below 0.001%.[31] In the United Kingdom, anaphylaxis accounts for 20 deaths per year, which represents 1 death in 3 million people.[32] According to the European Anaphylaxis Registry, a life-threatening or fatal anaphylaxis occurs in about 1 in 100 children experiencing severe anaphylaxis.[33]

There was a sevenfold increase in anaphylaxis admissions in England and Wales in 1992–2002.[34] Severe anaphylaxis was diagnosed in 1–9 per 10 000 people attending emergency departments in the United Kingdom, Australia, and the United States.[35] It is estimated that in a 12-month period, 1 in 12 patients with previous anaphylaxis will have a recurrence, and 1 in 50 will require hospitalization or treatment with epinephrine.[36]

Pathophysiology of Anaphylaxis

Although anaphylaxis is often subdivided into immunological and nonimmunological types, the clinical presentation is similar in both, and most authorities no longer make a distinction. Immunological anaphylaxis is further classified as IgE-mediated and non-IgE-mediated anaphylaxis. In IgE-mediated anaphylaxis, allergen cross-links allergen-specific IgE on the surface of mast cells and basophils, leading to their degranulation. Release of mediators causes bronchoconstriction, mucus secretion, diminished cardiac contractility, increased vascular permeability, vasoconstriction of coronary and peripheral arteries, and vasodilation of venules, thereby producing clinical symptoms of anaphylaxis. IgE-mediated reactions occur in presensitized patients (*e.g.,* those experiencing penicillin-, insulin-, latex-, or peanut-induced anaphylaxis). IgG- or IgM-related transfusion reactions should be classified as immunological, non–IgE-mediated anaphylaxis. In contrast, some substances, such as opioids, radiocontrast media, vancomycin, and some muscle relaxants, are capable of direct release of mediator (histamine) from basophils and mast cells without involvement of IgE. Although reactions to NSAIDs are considered pharmacological rather than immunological (because of the downstream effects of COX inhibition), an IgE-mediated mechanism has been suspected in a few patients but is difficult to prove. Apart from IgE, other antibodies may be involved: In murine models IgG-mediated FcγRIII-dependent anaphylaxis elicited by a high dose of allergen has been described. The key participating cells in this type of anaphylaxis are macrophages, with platelet-activating factor being the main mediator.[37]

Etiology of Anaphylaxis

Anaphylaxis is most commonly caused by foods, drugs, general anesthetic agents, insect stings, and latex. Rare causes include vaccines, semen, and aeroallergen inhalation. Exercise can occasionally cause anaphylaxis either on its own (exercise-induced anaphylaxis) or after ingestion of a food to which the individual is presensitized (food- and exercise-induced anaphylaxis). Up to 20% of patients with systemic mastocytosis present with anaphylaxis during their lifetime.[38] Anaphylaxis mostly occurs in reaction to hymenoptera stings, NSAIDs, and opioids and in the perioperative setting.[39] Idiopathic anaphylaxis accounts for up to 60% of anaphylaxis cases in ambulatory adults and for 10% of cases in children.[40] It is increasingly recognized that some anaphylactic cases are multifactorial. Cofactors are thought to lower the threshold for the induction of anaphylaxis and are implicated in about 30% of anaphylaxis cases in adults.[41] The risk of severe anaphylaxis is increased in patients taking beta-blockers or ACEIs, or both.[28]

The most common routes of allergen exposure are oral and parenteral, although inhalation of allergens (*e.g.,* fish or legume allergens after cooking, latex particles in health care settings) or percutaneous penetration after skin contact can induce anaphylaxis in highly sensitized patients.

Food-Induced Anaphylaxis

According to a meta-analysis of 34 studies, food-induced anaphylaxis was reported to occur with an incidence of 0.14 cases per 100 000 person-years at all ages and up to 7 per 100 person-years in children aged 0–4 years.[42] According to the European Anaphylaxis Registry, foods are a predominant cause of anaphylaxis in the first decade of life. Teenagers and young adults in their second and third decades of life are known to be at the highest risk of fatal food-induced anaphylaxis.[34]

Peanuts, tree nuts, fish, and shellfish are the most frequent culprits in food-induced anaphylaxis, but almost any food can be implicated. Many cases of severe anaphylaxis are caused by unintended exposure to hidden food allergens. In addition, cofactors, such as alcohol, NSAIDs, and exercise, may increase the severity of a food-induced allergic reaction.[27]

Drug-Induced Anaphylaxis

Drug-induced anaphylaxis is more common in hospitalized patients than in the community. Any drug can cause anaphylaxis, but the prevalence varies: one study found 5–15 cases per 100 000 hospitalized patients for most analgesics and antibiotics, whereas for dextran, penicillin, pentoxifylline, and streptokinase, the figure was over 30 cases per 100 000.[43] Anaphylaxis has been reported after treatment with monoclonal antibodies (mAbs; basiliximab, rituximab, infliximab, omalizumab, etc.).[44] IgE antibodies to galactose-α-1,3-galactose (α-gal) are thought to cause immediate anaphylaxis on first exposure to cetuximab.[45]

Drugs are known to be the leading cause of fatal anaphylaxis, with the mortality rate in drug-induced anaphylaxis about one death per 50 000–100 000 treatment courses.[46]

All routes of administration can potentially be fatal, including oral, intravenous, subcutaneous, intraarticular, intrauterine, inhalational, rectal, or topical, but the risk is greatest after parenteral administration.

Perioperative Anaphylaxis

Perioperative anaphylaxis occurs in up to 1 of 13 000 anesthesia administrations.[28] The common causes of perioperative anaphylaxis include neuromuscular-blocking agents, antibiotics, blood and blood products, dyes, chlorhexidine, or natural rubber latex.[28] Reactions to neuromuscular-blocking agents mostly occur on first exposure and have been associated with a 70% rate of cross-reactivity in this group; risk factors for fatal anaphylaxis include male gender, history of cardiovascular disease, emergency setting, and use of beta-blockers.[47] Latex remains an important cause of intraoperative anaphylactic reactions. The antiseptic chlorhexidine is increasingly recognized as a cause of IgE-mediated perioperative anaphylaxis.[48]

Insect Sting–Induced Anaphylaxis

Following insect stings, life-threatening systemic reactions have been reported in 0.4–0.8% of children and up to 3% of adults.[49] Severe anaphylaxis from insect stings causes approximately 40 deaths annually in the United States and nearly 100 in Europe.[49] Occupational anaphylaxis caused by venom allergy can occur in bee keepers, gardeners, forestry or greenhouse workers, farmers, truck drivers, and masons.[50] The severity of reaction depends on the type of insect, amount of venom, location of sting, the patient's sensitivity, older age, preexisting diseases, previous less severe systemic reactions, concomitant treatment, mast-cell disorder, and elevated baseline tryptase.[51] Allergen-specific immunotherapy with venom extracts has been shown to be safe and effective in patients with *Hymenoptera* venom allergy, providing some clinical protection within the first 8 weeks of treatment and a long-lasting effect after 3–5 years of maintenance treatment (Chapter 43). It is noteworthy that patients with systemic mastocytosis are at risk of potentially fatal anaphylaxis to insect stings even if they are not presensitized to venom: this may be attributed to venom components, such as phospholipase A2, acting as mast-cell liberators.[51]

Latex-Induced Anaphylaxis

The prevalence of latex allergy has been estimated to be as high as 1–6% in the general population, 8–17% in health care workers, and 67% in patients with spina bifida.[31] Latex-induced anaphylaxis has been reported in surgery and dentistry and can be fatal. More than half the patients with latex allergy report allergic reactions to fruits, such as banana, avocado, kiwi fruit, chestnut, pear, pineapple, grape, and papaya.

Other Rare Causes of Anaphylaxis

Anaphylaxis occurs during 1 in 20 000–47 000 transfusions of blood or blood products, especially in patients with IgA deficiency.[52] IgA deficiency affects 1 in 500–700 Caucasians. One-third of these patients have circulating anti-IgA antibodies, which are associated with serious life-threatening anaphylactic reactions to blood products containing IgA.[52] Seminal fluid allergy is extremely rare, mostly affecting young women with atopy, with 20% of cases developing life-threatening anaphylaxis. These reactions can be prevented with condom use or intravaginal desensitization with seminal fluid. In cystic echinococcosis, anaphylaxis can follow the rupture of a hydatid cyst during surgery or as a result of trauma.[53]

Anaphylaxis in Clonal Mast-Cell Disorders

There is a link between unexplained anaphylaxis and clonal mast-cell disease (systemic mastocytosis or monoclonal mast cell activation syndrome).[54] In systemic mastocytosis, anaphylaxis may occur to *Hymenoptera* stings and drugs (NSAIDs, opioids, and drugs used in the perioperative setting). Patients with unexplained anaphylaxis should be evaluated for mast-cell clonality to exclude systemic mastocytosis or mast-cell activation syndrome.[54]

Clinical Diversity of Anaphylaxis

In anaphylaxis, there is a remarkable range of clinical symptoms. Anaphylaxis can be preceded by prodromal symptoms, such as tingling and redness of the palms and soles, anxiety, sense of impending doom, and disorientation. Anaphylaxis most commonly begins in skin and mucous membranes, is followed by involvement of the respiratory and GI tracts and the cardiovascular system, and may finally proceed to cardiac and/or respiratory arrest. Generalized urticaria and angioedema are the most common manifestations of anaphylaxis, observed in over 90% of cases, but may be absent. Respiratory symptoms may vary from rhinitis to laryngeal edema and airway obstruction, which are potentially life threatening. Cardiovascular manifestations in anaphylaxis include hypotension and/or cardiac arrhythmias. In adults, reduced blood pressure is regarded as systolic blood pressure of <90 mm Hg or >30% decrease from that person's baseline values.[27] Some patients present with only cardiovascular collapse in the absence of other signs of anaphylaxis, especially during general anesthesia. Anaphylaxis is usually associated with tachycardia caused by increased cardiac sympathetic drive in response to a decreased effective vascular volume, but bradycardia may also occur. Anaphylaxis may result in up to 35% of intravascular fluid leaking into the extracellular space. A two-phase reaction to the hypovolemia may present with tachycardia as the first phase, followed by bradycardia when effective blood volume falls by 20–30%.[55]

CLINICAL PEARLS

Diagnosis of Anaphylaxis

- Anaphylaxis is characterized by extreme difficulty with breathing as a result of airway obstruction from angioedema/bronchoconstriction, circulatory collapse, or both.
- It is nearly always accompanied by tachycardia, usually by flushing, urticaria, and panic, and sometimes by vomiting and diarrhea.
- Panic attacks do not involve airways obstruction, hypotension, or urticaria but may be accompanied by faintness or tetany of the hands as a result of hyperventilation.
- Vasovagal attacks present with fainting, nausea, slow pulse, and pallor without respiratory difficulty, diarrhea, or urticaria.

Four clinical patterns of anaphylaxis have been described: immediate, biphasic, protracted, and delayed. Anaphylaxis can occur within seconds after allergen exposure: The more rapid the onset of anaphylaxis after allergen exposure, the more severe and life-threatening is the reaction. Food-induced anaphylaxis takes slightly longer to develop than drug- or insect-induced anaphylaxis. Some patients may have biphasic anaphylaxis, with recurrence after 1–72 hours, but usually within 8–10 hours of the initial attack.[28] According to a meta-analysis of 27 studies, patients with anaphylaxis presenting with hypotension or having an unknown trigger may be at increased risk of biphasic anaphylaxis.[56] Some patients may develop protracted anaphylaxis, which sometimes lasts longer than 24 hours, may be extremely severe, and is often resistant to treatment. Delayed onset of anaphylaxis has been reported anecdotally but is very rarely encountered in clinical practice.

The diversity and severity of symptoms in anaphylaxis depend on the dose of allergen, the route of allergen exposure, the extent of allergen absorption, the degree of sensitization, individual allergen threshold for a reaction, target tissue sensitivity, cofactor involvement, coexisting atopic diseases and their severity, and concomitant treatment. “Summation anaphylaxis” has been recognized as occurring after simultaneous exposure to various stimuli (physical exercise, infection, stress, or concomitant exposure to other allergens or treatment with NSAIDs, ACEIs, or beta-blockers).

Fatal reactions to foods are usually characterized by respiratory symptoms (bronchospasm and hypoxia). In contrast, anaphylaxis induced by insect stings is more likely to lead to cardiovascular collapse. Asthma sufferers are at higher risk of fatal anaphylaxis.[27] The risk of relapse in anaphylaxis depends on the type of allergen, individual allergen threshold, success of allergen avoidance, and the availability of immunotherapy.

The most dangerous symptoms are laryngeal edema, respiratory failure, and circulatory collapse, which may lead to death. Deaths from acute asthma in anaphylaxis occur predominantly in patients with preexisting unstable asthma. Rapid fatal shock often occurs without other symptoms, and laryngeal angioedema is the least common cause of fatality. Fatal anaphylaxis occurs mostly within an hour of the onset of anaphylaxis.[32] According to the UK Fatal Anaphylaxis Registry, the earliest arrest in fatal food anaphylaxis occurred within 25–35 minutes of exposure, slightly slower than with insect stings (10–15 minutes) or drugs (≤5 minutes in hospital and 10–20 minutes outside hospital).[32]

Diagnosis of Anaphylaxis

Measurement of blood tryptase is now widely used as a marker of mast cell degranulation for *in vitro* confirmation of anaphylaxis. Beta-tryptase is released from mast cells, but not from basophils, and diffuses more slowly compared with histamine. The concentration of tryptase peaks 1–2 hours after the onset of reaction, with a half-life of 1.5–2.5 hours. Samples for tryptase testing should be collected as soon as possible after emergency treatment of the patients and within 1–2 hours (but not later than 4 hours) of anaphylaxis onset, and again after 24 hours (baseline sample) to check that the value has returned to normal.[57] Tryptase may also be detected in postmortem specimens after death from suspected anaphylaxis.[58]

Normally, mature tryptase is below detection limits in the serum of healthy subjects, whereas it is elevated in most cases of anaphylaxis with vascular compromise, especially if it is parenterally induced. However, a normal tryptase result does not exclude anaphylaxis. Tryptase within the normal range during anaphylaxis is often observed in food-induced anaphylaxis. In infants, tryptase may not be elevated after anaphylaxis, although the baseline levels may be increased.[59] The diagnostic value of other mast-cell products, such as histamine, platelet-activating factor, and proteases (carboxypeptidase A3), in anaphylaxis is under investigation.

In anaphylaxis, component-resolved diagnosis can be useful to stratify risk in certain clinical scenarios.[60] For example, patients with wheat-dependent exercise-induced anaphylaxis should be tested for omega-5-gliadin sensitization,[61] whereas patients with anaphylaxis to vegetables, fruits, nuts, and cereals may have IgE to nonspecific lipid transfer proteins (mostly Pru p 3 and Tri a 14).[62] In delayed anaphylaxis to mammalian meat or anaphylaxis to cetuximab, tests for IgE against galactose-α-1,3-galactose (α-gal) should be considered.[45] Certain components are regarded as risk factors for anaphylaxis; for example, Mal d 3 sensitivity carries a sevenfold greater risk of anaphylaxis to apple compared with Bet v 1.[63]

Management of Anaphylaxis

Early recognition of anaphylaxis facilitates removal of the cause and prompt institution of treatment. The patient with anaphylaxis should lie down with the legs elevated to increase venous blood return and maintain cardiac output, and intravenous fluids should be given. In drug-induced or insect-induced anaphylaxis a tourniquet may be placed proximal to the site of the injection or insect sting to slow absorption of injected antigens. The tourniquet should be released for 3 minutes at 5-minute intervals, with the total duration of application not exceeding 30 minutes. Epinephrine should be administered by an intramuscular injection in the mid-outer thigh at the first sign of respiratory failure or cardiovascular collapse and repeated after 5–15 minutes if the response to the first injection is suboptimal.[25] Epinephrine autoinjectors for self-administration are available, but a single pen may be insufficient to reverse severe reactions. Use of these pens in anaphylaxis outside hospital can be lifesaving. Overall, prompt diagnosis of anaphylaxis, early administration of epinephrine, and fast transport to emergency rooms are crucial factors for successful management of anaphylaxis.

Epinephrine is both an α and β adrenergic agonist with cyclic adenosine monophosphate (cAMP)–mediated pharmacological effects on target organs. In patients with anaphylaxis, stimulation of α_1 adrenergic receptors increases peripheral vascular resistance, thereby improving blood pressure and coronary perfusion, reversing peripheral vasodilation, and decreasing angioedema. Activation of β_1 adrenergic receptors increases myocardial contractility (inotropy, chronotropy) while stimulation of β_2 adrenoreceptors causes bronchodilation and decreases the release of inflammatory mediators from mast cells and basophils.[27]

Current guidelines recommend the intramuscular route for epinephrine administration because of faster absorption and higher plasma level of epinephrine after intramuscular injection compared with subcutaneous injection.[25] The appropriate dosage of epinephrine is 0.01 mg/kg of a 1:1000 (1 mg/mL) solution, to a maximum of 0.5 mg in adults.[27] Epinephrine has a rapid but short action, so the dose may need to be repeated every 5–15 minutes until symptoms improve.[64] More than one dose is required in a third of patients. Intravenous administration of epinephrine should be reserved for severe anaphylaxis with profound life-threatening hypotension that is refractory to other treatment because of a risk of potentially fatal cardiac arrhythmias and myocardial infarction.[26] The recommended dose is a 1 : 100 000 solution (*i.e.,* 1 mg in 100 mL saline at initial infusion rate of 2–10 μg/min, titrated up or down, depending on the clinical response or epinephrine side effects).

Common pharmacological adverse effects of epinephrine include anxiety, fear, headache, pallor, tremor, dizziness, and palpitation. In the event of an overdose, unwanted effects may include increased Q–T interval on electrocardiography, ventricular arrhythmias, angina, myocardial infarction, increased blood pressure, pulmonary edema, and intracranial hemorrhage. Patients with cardiovascular diseases and thyrotoxicosis and cocaine users are particularly susceptible to the adverse effects of epinephrine.

The efficacy of epinephrine can be decreased by concomitant therapy with beta-blockers, which is associated with unopposed stimulation of α adrenoreceptors and reflex vagotonic effects, leading to bradycardia, hypertension, coronary artery constriction, bronchoconstriction, and augmented mediator release. Anaphylaxis in patients on beta-blockers can be severe, protracted, and unresponsive to treatment. Patients treated with beta-blockers may require fluid replacement and treatment with glucagon, which increases intracellular cAMP independently of β adrenergic receptors. Glucagon can be administered intravenously 1–5 mg (20–30 mg/kg in children, maximum 1 mg) over 5 minutes, followed by infusion at 5–15 mg/min titrated to clinical response.[26] Glucagon may improve hypotension in 1–5 minutes with maximal effect at 5–15 minutes. Side effects of glucagon include nausea and vomiting.

Corticosteroids are often administered in anaphylaxis to minimize the risk of recurrent or protracted anaphylaxis. The beneficial effects of corticosteroids develop 6–12 hours after administration. Therefore their main role in anaphylaxis is likely to be the prevention of relapse, but it is still unclear how they work.

If there is no response to epinephrine, life support measures should be instituted. The treatment choice depends on the clinical presentation. In hypotension, large volumes of fluids should be given rapidly using 1–2 L of 0.9% normal saline, infused rapidly (5–10 mL/kg within the first 5 minutes for an adult and up to 30 mL/kg in the first hour for children), to compensate for peripheral vasodilatation and for fluid loss into the extravascular space.[26] According to a Cochrane review, crystalloid normal saline should be preferred to colloids for intravenous fluid resuscitation.[65] Other vasopressors (dopamine, glucagon) may be needed to reverse severe hypotension. Oxygen should also be administered in circulatory or respiratory failure. Bronchospasm should be treated with nebulized or inhaled β_2 agonists. If there is severe laryngeal edema, endotracheal intubation and even emergency tracheostomy may be needed to maintain the airway. Methylene blue, a selective nitric oxide cyclic guanosine monophosphate (cGMP) inhibitor, can prevent vasodilatation and has been reported to be effective in refractory anaphylaxis.[66] Patients presented with respiratory compromise should be observed in a hospital setting for at least 6–8 hours.[27] In severe cases of hypotension, an observation period of 12–24 hours is advisable.[27]

Prevention of Anaphylaxis

The first step in prevention is to identify those at risk of anaphylaxis. Therefore all patients with a history of anaphylaxis should be referred for assessment and undergo allergy evaluation. Patients should be instructed how to avoid culprit allergens and cross-reactive agents and should be advised on safe alternatives. The education of patients, their families, and, in the case of children, caregivers and school staff about anaphylaxis, and availability of first-aid measures is of primary importance. Written personalized emergency action plans should be provided to patients at special risk, such as school children. Emergency medications, such as epinephrine autoinjectors, should be dispensed, and patients should receive training on their correct use. Patients should be advised to carry an epinephrine autoinjector with them at all times. Immunotherapy is very effective for prophylaxis of bee- and wasp venom–induced anaphylaxis in sensitized patients and can be lifesaving. Drug-induced anaphylaxis can be prevented by avoidance of culprit drugs and cross-reacting agents, by premedication (for radiocontrast media), and, in some cases, by drug desensitization for antibiotics, chemotherapeutic agents, insulin, vaccines, biological agents, and so on. For food-induced anaphylaxis, avoidance of the culprit food is essential; oral immunotherapy is available in some allergy centers. In idiopathic anaphylaxis, patients with frequent episodes (>6 episodes per year or ≥2 episodes within 2 months) can be treated with steroids to prevent further episodes. Omalizumab[67] and rituximab[68] have been reported to be effective in preventing idiopathic anaphylaxis. Prevention strategies for anaphylaxis should also involve promoting public awareness and public health measures, such as appropriate food labeling, disclosure of food ingredients in restaurants, withdrawal of peanuts from in-flight refreshments, first-aid training in anaphylaxis for school staff, and establishment of national anaphylaxis registries.

TRANSLATIONAL RESEARCH OPPORTUNITIES

ON THE HORIZON

- Defining the role of functional autoantibodies and understanding the mast-cell activation signals in chronic spontaneous urticaria should improve clinical assessment and management of patient subgroups.
- Development of new bradykinin and kallikrein inhibitors for patients with hereditary angioedema should further improve the acute management of this rare but very important condition.
- Understanding the full clinical spectrum of patients with cryopyrin-associated periodic syndrome with *NLRP-3* mutations should allow earlier identification and treatment of these individuals with interleukin-1 blockers to improve quality of life and prevent later complications.

Ongoing research into the importance of functional autoantibodies in chronic urticaria and the cause or causes of mast-cell activation in patients with “idiopathic” disease should help to refine clinical assessment and management pathways.

The effectiveness of a bradykinin receptor antagonist and a kallikrein inhibitor for emergency treatment of HAE has illuminated the key role of the kallikrein–kininogen–kinin pathway in disease pathogenesis. Development of new inhibitors of this pathway may offer additional benefits to patients in the future.

Clarification of the phenotypic spectrum of patients with cryopyrin-associated periodic syndrome with *NLRP-3* mutations will facilitate early detection of affected individuals who present in childhood with persistent urticaria and would benefit from treatment with IL-1 blockers. Early treatment should improve quality of life and may prevent the development of systemic amyloidosis, nephropathy, and deafness in adulthood.

MULTIPLE-CHOICE QUESTIONS

1. Urticaria is defined by:
   A. Itchy wheals, angioedema, or both
   B. Urticarial rash for >6 weeks
   C. An inducible elicitor
   D. Spontaneous wheals
   E. Recurrent angioedema without wheals

2. The main mediator of chronic spontaneous urticaria (CSU) is:
   A. Interleukin-1
   B. Bradykinin
   C. Tryptase
   D. Histamine
   E. Cysteinyl leukotrienes

3. The first line of management of urticaria is:
   A. Oral corticosteroids
   B. Diet
   C. Nonsedating H1 antihistamines
   D. Omalizumab
   E. Cyclosporin

4. The first-line treatment of anaphylaxis is:
   A. Subcutaneous epinephrine
   B. Intramuscular epinephrine
   C. Nonsedating H1 antihistamines
   D. Oral corticosteroids
   E. Parenteral corticosteroids

5. What is the treatment of choice for refractory anaphylaxis in a patient who is taking beta-blockers?
   A. Prednisolone
   B. Glucagon
   C. Hydrocortisone
   D. Loratadine
   E. Salbutamol

Allergic Reactions to Stinging and Biting Insects

Arthur Helbling, Ulrich R. Müller

Insects can induce allergic reactions by stinging and biting. They sting humans to defend themselves; they bite to feed. With regard to allergies, stings by insects of the order Hymenoptera (bees, wasps, or ants) are much more important than bites, which can be inflicted by various insects, such as mosquitoes, horseflies, midges, fleas, and bed bugs. Hymenoptera stings can induce acute systemic allergic reactions that kill several hundred patients in Europe and America every year, whereas systemic allergic reactions to bites are very rare. Both stings and bites can induce local allergic or toxic reactions. Infections are only transmitted by bites.

ENTOMOLOGICAL ASPECTS[1-4]

Stinging Hymenoptera all belong to the suborder Aculeatae (Fig. 43.1) with the families Apideae, Vespidae, Formicidae, and Myrmicinae. Latin and popular names in English, which partly differ in Europe and the United States, are given in Table 43.1.

Apidae

In this family, the honeybee (*Apis mellifera*) (Fig. 43.2A) is clinically the most important cause of allergies. Stings occur either in the vicinity of beehives or when the insect feels threatened during human activities, such as cutting flowers or walking barefoot in the grass. Because the whole beehive survives over winter, stings can occur not only in spring and summer but occasionally also on warm winter days. Honeybees are brown and moderately hairy. In contrast to other Hymenoptera, they usually lose their barbed sting when stinging.

Bumblebees (*e.g., Bombus terrestris*) are increasingly used as pollinators in greenhouses and occasionally cause allergic sting reactions in greenhouse workers.[2] Bumblebees are distinctly larger and more hairy compared with honeybees, and most species have distinct yellow or white bands on their abdomen (Fig. 43.2B).

Vespidae

The vespids are divided into the subfamilies Vespinae and Polistinae, which differ morphologically in the junction between thorax and abdomen (Figs. 43.2C, D). Vespids are almost hairless, and in most species, the abdomen is striped black and yellow. Vespids do not usually lose their sting when stinging and may therefore sting several times, even the same victim. Because only the queen survives over winter, larger populations develop only in summer, and most stings occur in summer and fall. The subfamily Vespinae contains the three genera *Vespula, Dolichovespula,* and *Vespa.*

Vespula (*V. germanica* and *V. vulgaris* in Europe; *V. maculifrons* and *V. germanica* in the United States) are called *wasps* in Europe and *yellow jackets* in the US. They breed in the ground, in attics, or in shelters. The genus *Vespula* is, by far, the most aggressive. Stings occur not only near the nests but also more often while victims are eating outdoors.

Most species of *Dolichovespula* (*D. media, D. sylvestris, D. saxonica* in Europe; *D. maculata, D. arenaria* in the United States) look very similar to *Vespula,* with black and yellow stripes on the abdomen and only a slightly larger size. They can be distinguished from *Vespula* by the larger distance between the eyes and the mandibles. Only *D. maculata,* the bald-faced hornet in the United States, is easy to distinguish from other vespids by its mostly black abdomen. *Dolichovespula* build their nests in tree branches or under the roofs of houses. They sting almost exclusively in the vicinity of their nests.

The genus *Vespa* (*V. crabro,* the European hornet[Fig. 43.2E]; *V. orientalis*) is easy to distinguish from other vespids by its much larger size. The European hornet was brought to America in the late nineteenth century, whereas the Asian hornet (*V. velutina*) has recently (2005) been introduced to the South of France. The oriental hornet is present in southeastern Europe, Asia, and Africa.

Nevertheless, hornet stings are rare and occur almost exclusively in the vicinity of nests, which are usually in hollow tree trunks or bird nesting-boxes.

Polistinae (*P. annularis, P. exclamans, P. fuscatus,* "paper wasp" in the United States; *P. dominulus, P. gallicus, P. nympha,* "field wasp" in Europe) live mostly in the southern United States and in the Mediterranean area of Europe, but small colonies have been observed all over Europe except in the British Isles. Their small nests consist only of one womb and are built in trees or under roofs.

Ants (Myrmicinae, Formicinae)

In South and Central America, and in the southern states of the United States, fire ants (*Solenopsis invicta*[see Fig. 43.3F]; *S. richteri*) are responsible for many systemic allergic sting reactions.[3] Fire ants build their mounds in yards, playgrounds, and fields. Occasional allergic sting reactions to *Pogonomyrmex,* the North American harvester ant, have been described and extremely rarely to the European red ant, *Formica rufa.* In contrast, species of Myrmicinae, especially *Myrmecia pilosula,* the "jack-jumper ant," are an important cause of allergic sting reactions in southern Australia.[4] Another group of aggressive ants are the ponerinae of the genus *Pachycondyla,* including *P. chinesis* in the Far East

Polistes spp.	Field wasp	Paper wasp
Solenopsis invicta	—	Fire ant

and *P. senna arensis* in the Middle East, which may also cause systemic allergic reactions.[3]

ALLERGENS IN HYMENOPTERA VENOMS

All Hymenoptera venoms contain low-molecular-weight substances, such as biogenic amines, phospholipids, amino acids, and carbohydrates, as well as peptides, such as melittin, apamin, and kinins, which contribute to the toxic effect but which—except melittin—are probably irrelevant with regard to allergies. The allergens of the important stinging Hymenoptera are shown in Table 43.2. Most of them are glycoproteins of 10–50 kilodaltons (kDa) and some, for example, dipeptidylpeptidases, are glycoproteins of up to 102 kDa.[5] The major allergens in bee venom are phospholipase A2, hyaluronidase, and acid phosphatase; in vespid venoms, antigen 5 and phospholipase A1. Ant venom from *S. invicta* contains a 37-kDa allergen and a 24-kDa allergen, with some sequence homology to phospholipase A1 and to antigen 5 from vespid venom.[3] In ant venom from *M. pilosula*, only pilosulin 1 has been identified as a major allergen so far. The genes of many major venom allergens have been cloned, and many of them have also been expressed as recombinant proteins comparable in allergenic activity and enzymatic function to their natural counterparts (see Table 43.2).[6-9] The amount of venom injected during a sting varies between and within species, especially in vespids. Bees release 50–140 μg venom per sting and vespids much less: between 2 and 17 μg.[2]

CLINICAL PICTURE

CLINICAL RELEVANCE

- Not every swelling after an insect sting is caused by allergy.
- Hymenoptera venom allergy is generally caused by systemic IgE.
- Although Hymenoptera venom allergy is not as prevalent as respiratory allergies, severe systemic reactions—even fatal—occur regularly worldwide.

Symptoms of venom hypersensitivity are most often caused by immunoglobulin E (IgE)-mediated immunological mechanisms, but occasionally by non–IgE-mediated immunological mechanisms. Rarely, nonimmunological mechanisms of mediator release play a role. The clinical presentation is classified into normal, large local, systemic allergic, systemic toxic, and unusual reactions.[1,2]

Normal Local Reactions

The normal local reaction of a nonallergic subject to a Hymenoptera sting consists of a painful, sometimes itchy, local wheal

and flare reaction, followed by a swelling of up to 5–10 cm in diameter. Usually, local symptoms resolve within a few hours. The fire ant (*S. invicta*) attaches to the skin by means of its powerful mandibles and then stings, releasing venom that produces a characteristic firelike pain. If not removed, it will continue to rotate in a pivotal fashion, repeatedly injecting further small amounts of venom.[10] After the ant stings, a vesicle is left behind, which later develops into a pustule that only heals after 1–2 weeks.[3]

Large Local Reactions

Large local reactions (LLRs) are defined as swellings around the sting site exceeding 10 cm in diameter, developing minutes to hours after the sting and lasting more than 24 hours.[1] LLRs may cause significant discomfort, especially when they last for days or even weeks and involve a whole limb, eyelids, or lips. Sometimes they are accompanied by lymphadenopathy or lymphangitis. They may also be associated with nonspecific systemic inflammatory symptoms, such as malaise, fever, shivering, or headache. However, the development of local infection, abscesses, or a phlegmon at the sting site is inhibited by the bacteriostatic effect of Hymenoptera venoms. In contrast, scratching after stings by the American fire ant or bites from blood-sucking insects, such as midges, can lead to skin infection.

The pathogenesis of LLRs is thought to be based on IgE-mediated and/or cell-mediated immune mechanisms, most likely a combination of both.[1,2]

Systemic Reactions

Systemic reactions (SRs), including anaphylactic reactions, are usually mediated by IgE (Chapter 42). Affected organs include skin (pruritus, urticaria, flush, angioedema), the gastrointestinal (GI) tract (cramps, vomiting or diarrhea, dysphagia), the respiratory tract (laryngeal edema, bronchial obstruction, pulmonary edema), and the cardiovascular system (arterial hypotension, shock, arrhythmias, loss of consciousness with incontinence).

The most commonly used classification of SRs was developed by Müeller.[11] Symptoms appear most often within a few minutes to 1 hour after the sting. The patient recovers usually within a few hours. A protracted course over more than a day or a biphasic course has been described but is rare.

Lasting morbidity, for example, myocardial or cerebrovascular infarction, as a consequence of SRs or even fatal reactions can occur, but these are rare (see "Epidemiological aspects").

Systemic Toxic Reactions

Toxic reactions are dose dependent, and a clinically significant toxic effect only needs to be considered after multiple stings—usually 50 to several hundred.[1,2] The main toxic effects develop within hours to days and comprise rhabdomyolysis and intravascular hemolysis leading to acute renal failure with tubular necrosis. Myocardial damage, hepatic dysfunction, coagulation disorders, and brain edema and/or necrosis may occur. The number of stings needed to cause a fatal reaction in adults varies between 200 and 1000. In small children, however, fewer than 50 stings may be lethal. In most cases, death is not immediate but occurs after several days.

Unusual Reactions

Various unusual sting reactions can occur: these are rare and appear after hours to days. More than half of them follow immediate local or SRs.[1,12] Non–IgE-mediated immunological mechanisms are likely involved. The causal relation to the sting event often remains uncertain. Serum sickness–like syndromes with fever, arthralgias, exanthema, and lymphadenopathy are well documented. Less frequently reported complications of Hymenoptera stings include diseases of the nervous system (peripheral neuropathy, polyradiculomyelitis, extrapyramidal syndromes, acute disseminated encephalomyelitis), kidneys (glomerulonephritis, interstitial nephritis), or blood and blood vessels (hemolytic anemia, thrombocytopenia, Henoch-Schönlein syndrome and other forms of vasculitis). In these situations, a causal relation to the sting is less well documented.

EPIDEMIOLOGICAL ASPECTS

Prevalence of Allergy to Stings by Flying Hymenoptera

KEY CONCEPTS

- Awareness of the most relevant insects, specifically Hymenoptera and their entomological subdivisions, causing immunoglobulin E (IgE)–mediated allergies
- Assessment of clinical symptoms and classification of Hymenoptera venom allergy
- Evaluation of persons and circumstances at risk for Hymenoptera venom allergy
- Knowledge of appropriate diagnosis of Hymenoptera venom allergy, potential diagnostic and therapeutic control test tools

Cumulative lifetime sting rates of 61–95% have been reported in people aged 16–65 years. Of course, this can vary considerably in different regions of the world. Asymptomatic sensitization with the development of specific IgE to bee and wasp venoms is a frequent finding and has been reported in up to 40%.[13] Hymenoptera sting allergy can occur at any age. In general, because of their higher level of outdoor activities, men are more frequently stung compared with women, and children more often compared with adults.[14]

The reported cumulative lifetime prevalence of LLRs ranges from 2% to 26%, that of SRs from 0.3% to 5%.[2] Among beekeepers, it varies between 14% and 43%.[15] LLRs are not predictive for SRs in the event of a subsequent Hymenoptera sting.[13] In Europe and the United States, SRs are more frequently caused by vespids than by honeybees. In the southern states of the United States and in Australia, ants are important causes of SR.

Risk Factors for Hymenoptera Allergy

The risk of developing a sting allergy increases with the number of stings, especially if two stings occur within a short period (up to 2 months).[16] However, beekeepers stung less than 10 times a year have a much higher risk for SRs compared with those stung more than 200 times a year.[15] Even after successful venom immunotherapy, the risk of recurrent SRs after Hymenoptera stings persists throughout life.[17] Cardiovascular diseases and their treatment with β-blocking drugs and angiotensin-converting enzyme (ACE) inhibitors are associated with more severe sting reactions, sometimes also with lasting morbidity caused by cardiac or cerebrovascular infarction as a result of anaphylaxis.[1,18,19] However, β-blockers do not increase the overall risk of systemic sting reactions.[18] Systemic mastocytosis (indicated by elevated baseline serum tryptase) is a risk factor for severe or even fatal systemic sting reactions.[19] Atopy is not more frequent in patients with Hymenoptera sting allergy than in the general population. However, in patients with atopy and Hymenoptera venom allergy,

Mild SRs adults	Blaauw, 1985	CH		31	10	
Severe SRs in adults	Blaauw, 1985	CH	44	60	33	
SR in controls of controlled studies	Hunt, 1978	CH	58			
	Müller, 1979	FS		75		
	Brown, 2003	CH				72

Summarized in Rueff, Przybilla, Müller et al Allergy 1996;51:21-25. FS, field sting; CH, sting challenge.

SRs may be more severe and more often affect the respiratory tract. About 50% of beekeepers with venom allergy have atopy, and they may become sensitized by inhaling dust containing venom when working with beehives.[15]

Mortality Caused by Hymenoptera Stings

Mortality resulting from Hymenoptera stings varies from 0.09 to 0.48 deaths per million persons per year.[20] Over the past 40 years, the mean annual incidence of fatal Hymenoptera sting reactions in Switzerland has been 3.1; when extrapolated to the whole of Europe, this would be about 200. The vast majority of fatal sting reactions occur in adults over 45 years of age.[2,20] Additional risk factors include a positive history of sting allergy, male gender, and stings on the head or neck. Autopsies have documented preexisting cardiovascular disease in most cases.[20] Approximately half of the deaths occur in subjects with no known prior history of allergic sting reactions.

Natural History of Hymenoptera Sting Allergy (Table 43.3)

In prospective clinical studies, after an LLR, the risk of developing an SR to the next sting is between 5% and 10%; after a mild SR, the risk is between 15% and 30%; and after a severe SR, the risk is between 50% and 75%.[13,21] The severity of an index sting reaction is an important factor determining the risk at reexposure. Children are at lower risk of re-sting SR compared with adults.[1,22] The re-sting SR risk is definitely lower in patients with *Vespula* allergy than in those with bee venom allergy, probably because of the smaller and more variable amount of venom injected.

Epidemiological Aspects of Allergic Reactions to Ant Stings

Nearly 50% of inhabitants are stung each year in areas of the United States that are fire ant endemic.[3,10] Many report LLRs, but up to 1% of patients who are stung by imported fire ants develop anaphylaxis, and some deaths have been reported. In Australia, more than 90% of ant venom anaphylaxis is caused by *M. pilosula.* Age >35 years, annual sting rate, and allergy to bee venom were predictive factors for more severe reactions.[23]

DIAGNOSIS

History

As in all forms of allergy, the clinical history is key to diagnosing Hymenoptera sting allergy. This includes the date, number, and circumstances of stings (*e.g.,* environment, activities); kind and severity of symptom; sting site; retained or removed stinger; interval to onset of symptoms; emergency treatment; risk factors for a particularly severe reaction (*e.g.,* comorbidity, drugs, elevated baseline serum tryptase); tolerated stings after the first SR; reduction of the quality of life[24]; and other allergies.[1,2] In individuals with only LLRs, no further diagnostic tests are recommended. For those with SRs, diagnostic tests include skin tests, venom-specific serum IgE antibodies, and, in severe SRs, baseline serum tryptase.

Skin Tests

Skin tests should not be performed until at least 3 weeks after an SR, as false-negative results can occur (the refractory period). They are performed by intradermal or skin prick endpoint titration.[2] Injection of 0.02 mL of venom solution is given intradermally in increasing concentrations—0.00001–1 µg/mL—into the volar surface of the forearm. For skin prick tests, concentrations of 0.01–300 µg/mL are used. However, even at 300 µg/mL, the sensitivity of skin prick is clearly lower than that of the intradermal test. We therefore prefer the intradermal test.

Venom-Specific Serum IgE Antibodies

Several different *in vitro* immunoassays for the detection of venom-specific serum IgE antibodies (sIgE) are commercially available (Chapter 95). Immediately after a sting, sIgE may be low or undetectable, but it usually increases within days or weeks after an SR. If no sIgE is found in a patient with a clear history of venom allergy, the test should be repeated after 2–4 weeks.[2]

Elevated sIgE levels after Hymenoptera stings that cause a normal sting reaction are not predictive for future development of an SR. [13] sIgE can be determined against the whole venom or components of the venoms. Measuring sIgE to recombinant venom allergens has improved the precision of allergic diagnostic tests. Tests are currently available for the species-specific, nonglycosylated major allergens Api m 1, Api m 10, Ves v 5, and Ves v 1. Tests for Api m 2, Api 3, and Api m 5 will be available soon.[6,25]

Sensitivity and Specificity of Skin Tests and sIgE

The sensitivity of these tests is >90% in patients with a history of SR within the past year and decreases steadily thereafter with or without venom immunotherapy but may stay positive for many years. However, their specificity is limited, since up to 20% of an unselected population have positive results, whereas only 0.3–5% have a history of allergic sting reactions.[1,2] As a rule, the intradermal test result remains positive longer than that of sIgE. However, there is currently no reliable test that predicts the risk of future SRs in untreated or treated patients. Despite a history of typical SRs to stings, a few patients have no detectable sIgE and have negative skin test results.[26] This may be attributed to insufficient sensitivity of the available tests, a long interval between the SR and testing with spontaneous decrease of sensitization, or non–IgE-mediated pathogenesis.

Specificity may cause problems: more than 20% of people without a history of SR have a positive diagnostic test result.[13] Although it is difficult to exclude sensitization after a previous sting, this positivity may reflect cross-reactivity (see below).

For skin testing and venom immunotherapy for fire ant (*S. invicta*) stings, only whole-body extracts are currently available. These extracts have good sensitivity but low specificity. Therefore they should only be used in patients with a history of systemic sting reactions, at least 30 days after the SR.[10] In contrast, venoms of *M. pilosula* have been shown to have excellent sensitivity and specificity.[4]

Cross-Reactivity

Cross-reactivity between venom allergens is strong between species within a family, for example, among *Vespula, Dolichovespula,* and *Vespa,* but only limited between *Vespinae* and *Polistinae* or between honeybees and bumblebees.[6] There is some homology at the protein level between bee and vespid venoms, with ~50% sequence identity between the hyaluronidases and dipeptidylpeptidases of the two families, but double-positivity with diagnostic tests to both venoms is frequently observed. This may reflect true double-sensitization or cross-reactivity. Cross-reacting carbohydrate determinants (CCDs) are present in many major Hymenoptera venom allergens, such as hyaluronidase, acid phosphatase, and phospholipase A2, but also in many plant proteins (*e.g.,* rapeseed pollen or bromelain). CCDs are certainly responsible for a significant proportion of the double-positivity of diagnostic tests to bee and vespid venoms. They may also explain why individuals with no history of SRs have positive test results. The CCDs are probably of no clinical relevance.[27] The radioallergosorbent test (RAST)for venoms and CCDs can help distinguish between true double-sensitization and cross-reactivity but is not always conclusive.

Assessing IgE antibodies to species-specific nonglycosylated, recombinant major allergens (Api m1 [phospholipase A2] of bee venom and Ves v5 [antigen 5] of *Vespula* venom) reduces the rate of double-positivity very significantly and is helpful in choosing venoms for immunotherapy.[6,25,28]

Some cross-reactivity between allergens of vespid venoms and those of *S. invicta* has also been documented.[3,6]

Cellular Tests

If routine tests in patients with a history of SRs are negative, cellular tests may be helpful to demonstrate sensitization.[2]

In the *basophil histamine release test* peripheral blood leukocytes are incubated with venom allergens. The reaction with cell-bound IgE antibodies leads to histamine release from basophils. In the cellular antigen stimulation test (CAST), leukocytes of patients are prestimulated with interleukin-3 (IL-3) and exposed to venom allergens. The released sulfidoleukotrienes are determined by using enzyme-linked immunosorbent assay (ELISA).

The basophil activation test (BAT) is based on flow-cytometric demonstration of an altered membrane phenotype of basophils stimulated by IL-3 and allergen exposure. At present, the most commonly used expression marker is CD63. The sensitivity and specificity of BAT seems to be superior to skin tests and venom-specific sIgE. It may also have better predictive value. The test must, however, be performed with fresh blood; it is expensive and not yet well standardized: there are few data on specificity and predictive value in relation to a sting reexposure during or after venom immunotherapy.

Allergen-Specific IgG

The presence of sIgG and IgG4 primarily reflects exposure to the respective venom. sIgG titers increase after a sting, irrespective of the presence or absence of an allergic sting reaction. Venom immunotherapy induces a rise in sIgG. However, there is no close correlation between the concentration of sIgG or the sIgE/sIgG ratio and the clinical response to a resting during or after venom immunotherapy.[1] Routine assessment of sIgG is therefore not recommended but may be helpful if the responsible insect is unidentified.

Baseline Serum Tryptase

Because elevated baseline serum tryptase levels (>11.4 μg/L) are associated with severe, sometimes IgE-negative, systemic sting reactions and with cutaneous or systemic mastocytosis, this enzyme should be determined in all patients with a history of SRs.[19] The commercially available fluorescence immunoassay measures total tryptase. α-Tryptase is secreted continuously and reflects whole-body mast cell load. Elevated values are seen in cutaneous and systemic mastocytosis. β-Tryptase is released during mast cell activation and is a marker of anaphylaxis.

Sting Challenge Tests

Sting challenge with a live insect is not recommended as a diagnostic tool in untreated patients, but a sting challenge under well-supervised clinical conditions may be helpful in evaluating the efficacy of venom immunotherapy.[21,29] However, a tolerated sting challenge does not definitely exclude a reaction to future stings after immunotherapy, especially if these are repeated.[17]

PREVENTION AND TREATMENT

Prevention

All patients with a history of SRs should receive detailed instruction on the avoidance of future stings and measures to take if stung.[1] Bee stings occur most often when walking barefoot on grass, and wasp stings occur when eating outdoors, in orchards with fallen fruits, and near open waste-bins. The risk of a sting is especially high near beehives or vespid nests. While gardening, wearing long trousers, shirts with long sleeves, and gloves are recommended. Strongly scented perfumes, sun creams, or shampoos, as well as brightly colored garments, should be avoided.

Treatment of Large Local Reactions

Oral antihistamines and cooling of the sting site (*e.g.,* with ice cubes) reduces local swelling, pain, and itching. Antiinflammatory ointments or topical corticosteroids may diminish the local inflammatory process. In cases of severe swellings, oral corticosteroids together with antihistamines over several days are recommended.[10]

Systemic Allergic Reactions

Sympathomimetics, antihistamines, and corticosteroids are the most effective drugs for symptomatic treatment of SRs. All patients experiencing SRs should seek medical advice and should be medically observed until the symptoms resolve and blood pressure is stable.

Mild reactions confined to the skin may be treated with rapid-acting oral antihistamines alone. If respiratory or cardiovascular symptoms occur, intramuscular epinephrine must be given immediately, intravenous (IV) access should be established, and antihistamines and corticosteroids given intravenously (Chapter 42). All patients with severe SRs should be hospitalized and supervised until they recover completely. Patients with cardiovascular symptoms must be treated and transported in the supine position, and IV volume replacement is indicated.

Subsequently, every patient who has experienced a systemic allergic sting reaction should be investigated with a view to prevention measures and immunotherapy.[10]

Emergency Medication Kit

All patients with a history of SRs should carry an emergency kit for self-administration.[30] After a sting, patients should immediately take both antihistamines and corticosteroids, whether or not symptoms occur. In case of systemic symptoms, such as urticaria, dyspnea, generalized weakness, or dizziness, epinephrine should be administered intramuscularly via an autoinjector, such as the Epipen (dosage 0.3–0.5 mg of epinephrine).[30] In children with body weight <25 kg, Epipen Junior (0.15 mg epinephrine) or an equivalent product should be administered, along with half the adult dose of antihistamines and corticosteroids. If any SR occurs, medical care must be sought immediately.

Venom Immunotherapy[1,10]

Indications

Venom immunotherapy (VIT) is indicated in children and adults with a history of severe SRs (grade III/IV), provided sensitization to the relevant venom has been demonstrated by skin and/or blood test. LLRs or unusual reactions do not require VIT. VIT is also recommended for patients who experience repeated mild, non–life-threatening reactions and are at high risk for reexposure, such as beekeepers or their family members. Concomitant cardiovascular disease, mastocytosis, and strongly impaired quality of life because of the venom allergy are relative indications for VIT in patients with non–life-threatening sting reactions.[19,24]

Contraindications for VIT are the same as for immunotherapy with other allergens (Chapter 91).

Dosage and Treatment Regimens

The recommended maintenance dose for both children and adults is 100 µg of the venom. This maintenance dose is equivalent to approximately two bee stings or several vespid stings. A higher dose (*e.g.,* 200 µg) is recommended when SRs occur after reexposure to a field sting or a sting challenge.[29] In highly exposed subjects, such as beekeepers or professional gardeners, a maintenance dose of 200 µg is advised.

VIT may be initiated by a conventional or an ultra-rush protocol. During the first year, maintenance VIT is given every 4 weeks. Subsequently, the intervals may be extended to 6 weeks if VIT is well tolerated.

Adverse Reactions to VIT

The overall incidence of systemic adverse reactions to VIT varies between 5% and 40%.[1,10] VIT with bee venom causes side effects more often than with *Vespula* venom.[29] Ultra-rush protocols are associated with a higher rate of side effects compared with conventional protocols. Most systemic side effects are mild; only one-third of patients require medical treatment.

Premedication with antihistamines reduces large local and other cutaneous reactions, such as urticaria, but severe SRs may not be suppressed. Some units routinely give antihistamines 2 hours before up-dosing injections until the maintenance dose has been repeatedly well tolerated. In patients with recurrent SRs during up-dosing, off-label use of anti-IgE (omalizumab) has made it possible to complete up-dosing and to continue maintenance VIT.[31]

Efficacy of VIT

In addition to three prospective controlled trials, the efficacy of VIT has been confirmed by well-tolerated sting challenges during VIT in several uncontrolled prospective studies.[1,10] Full protection is achieved in 80–85% of patients receiving bee venom and in 95–100% of patients receiving *Vespula* venom. The higher risk of treatment failure in bee venom allergy may relate to differences in venom compositions. Important allergens, such as Api m10 or Api m 3, may be missing or present in low concentrations in some VIT products.[32] It has therefore been suggested that patients with a predominant sensitization to these allergens may not be properly protected by VIT.[33]

The efficacy of immunotherapy with commercially available whole-body extract of the ant *Solenopsis* has not been documented in controlled studies. However, excellent results, comparable with those of VIT with *Vespula* venom, were obtained in a double-blind placebo-controlled study using *M. pilosula* venom.[4]

Duration of VIT[17]

Lifelong treatment may be the safest recommendation, but in most allergy centers, VIT is given for up to 5 years. If VIT is given for at least 3 years, >80% of both adults and children are still protected, when reassessed 1–7 years after discontinuation. Longer courses of treatment should be considered in high-risk patients, such as those with very severe systemic sting reactions, coexisting cardiovascular or pulmonary disease, and systemic allergic reactions to VIT or stings during VIT and in subjects with elevated basal serum tryptase levels. Lifelong VIT is advised for patients with cutaneous or systemic mastocytosis.[10]

Risk Factors for Recurrence of SRs After Stopping VIT

A number of risk factors have been identified for relapse of Hymenoptera venom allergy after discontinuation of VIT[17]: in general, adults, especially older people, because of concomitant diseases, have a less favorable prognosis compared with children. Patients with bee venom allergy have a higher relapse risk compared with those allergic to *Vespula* venom. Patients with more severe pretreatment reactions and those with more SRs during VIT (to injections or field stings) have a higher risk for recurrent SRs to Hymenoptera stings. The risk of relapse is lower after 5 years of VIT, compared with only 3 years of VIT.

ALLERGIC REACTIONS TO BITING INSECTS

Biting insects may cause local allergic reactions as a result of sensitization to their salivary proteins introduced during the process of blood sucking. Systemic reactions are very rare. The responsible insects belong to the orders Diptera, Hemiptera, and Siphonaptera (Fig. 43.3).[34]

Clinical Symptoms

Local reactions to insect bites may be characterized by immediate wheal and flare, or may be delayed, with pruritic erythema and papules developing after 12–24 hours and lasting for days to weeks; combined reactions can also occur. In delayed and combined reactions, vesicular, bullous, or even necrotic lesions may develop. SRs are much rarer than those to Hymenoptera stings. They have, however, occasionally been described, especially after bites by horseflies (*Tabanus* spp.) and the kissing bug (*Triatoma protracta*).

Allergens

The salivary proteins involved have either digestive (amylases, esterases) or hemostatic function (*e.g.*, factor Xa inhibition). Numerous IgE-binding proteins with a molecular weight of 15–81 kDa have been described, especially in the saliva of mosquitoes, and in horseflies and kissing bugs as well; some of these proteins have been cloned.[35]

Prevention and Treatment

The application of insect repellents and prophylactic intake of antihistamines can prevent or mitigate outdoor exposure. Screens on windows and doors and mosquito nets over the beds are effective in homes. Bedbug infestation should be eliminated by using appropriate pesticides; flea infestation of pet animals should be managed by a veterinarian. Local reactions may be treated with topical steroids or oral antihistamines.

ON THE HORIZON

The availability of recombinant venom allergens offers several promising perspectives for diagnosis and immunotherapy.[5-9]

- The specificity of these tests could be considerably improved by using recombinant cocktails with species-specific major allergens without cross-reacting carbohydrate determinants (CCDs) for diagnosis instead of the whole venom.
- In patients with double-positive diagnostic tests to honeybee and *Vespula* venom, recombinant species-specific nonglycosylated major allergens from honeybee and *Vespula* venom make it possible to distinguish reliably between true double sensitization and cross-reactivity, an important issue for the choice of venoms for immunotherapy.
- Addition of such allergens to therapy solutions can increase the efficacy of venom immunotherapy (VIT) with bee venom, as these are lacking or insufficiently represented in currently available preparations.
- Allergic side effects of VIT might be reduced by using modified major allergens with reduced immunoglobulin E (IgE) binding, but retained specific T-cell interaction.[36]

MULTIPLE-CHOICE QUESTIONS

1. Which factor has NO influence on the severity of an allergic reaction as a result of a Hymenoptera sting?
   A. Elevated basal tryptase
   B. Treatment with β-blockers
   C. Two yellow jacket stings within 3 weeks
   D. Atopy
   E. Previous repeated severe allergic sting reactions

2. The average amount of venom released by a single bee sting is approximately:
   A. 0.5 μg
   B. 5 μg
   C. 50 μg
   D. 0.5 mg
   E. 0.5 g

3. Which important bee allergens are missing or found only in small concentrations in some therapeutic products used for venom immunotherapy (VIT)?
   A. Api m 1
   B. Api m 2
   C. Api m 4
   D. Api m 6
   E. Api m 10

4. Concerning the duration of VIT with Hymenoptera venoms, which statement is correct?
   A. Once the maintenance dose of 100 μg can be given without any side effect, VIT can be discontinued.
   B. The recommended duration of VIT is 3–5 years.
   C. Most patients will need a lifelong VIT.
   D. Once the patient on VIT has tolerated a sting of the relevant insect, VIT can be stopped.
   E. The duration of VIT—analogue to pollen immunotherapy—is maximally 3 years.

Atopic and Contact Dermatitis

Mark Boguniewicz, Luz Fonacier, Donald Y.M. Leung

Atopic dermatitis (AD) and contact dermatitis (CD) are common inflammatory skin diseases.[1,2] The complex pathophysiology of AD involves both underlying skin barrier abnormalities and immune dysregulation. Its course is augmented by environmental influences, including stress, allergen exposure, and microbial infection. Patients with AD experiencing a relapsing course benefit from a proactive approach with skin emollients and antiinflammatory therapy (*e.g.,* intermittent use of a topical steroid or calcineurin inhibitor). The identification of new immune pathways associated with AD has resulted in the development of novel biologicals targeting patients with refractory AD.

CD is a skin disorder caused by contact with an exogenous substance that elicits an allergic and/or irritant response. Allergic contact dermatitis (ACD) accounts for 20%, whereas irritant contact dermatitis (ICD) accounts for 80% of all cases of CD. ACD is a delayed-type, T cell–mediated immune response consisting of an afferent limb and an efferent limb. Irritants cause direct activation of the innate immune system through hyperproduction of cytokines and chemokines. The management of ACD includes identification of the allergen, avoidance, pharmacological intervention, and prevention. This chapter reviews the clinical and mechanistic aspects of both AD and CD.

CLINICAL ASPECTS OF ATOPIC DERMATITIS

Epidemiology

Prevalence of AD has been documented in up to 24% of children, with no apparent difference seen between urban and rural districts or between the two sexes. Children from families with atopy have a significantly higher risk of developing AD. Data from an international study (ISAAC Phase 3) showed that prevalence of current eczema in children varies widely among countries, ranging from 0.9% to 22.5%, and in adolescents, the prevalence ranges from 0.2% to 24.6%.[3] These data point to the significance of AD being a global health problem in both developed and developing countries and suggest that the ultimate presentation of an atopic disease may depend on a complex interaction between environmental exposures and end-organ response in genetically predisposed individuals. Prevalence of adult eczema from a nationally representative sample found that the 1-year prevalence of eczema was 10.2% and that the 1-year prevalence of eczema with asthma and/or hay fever was 3.2%.[4]

Natural History

AD typically manifests in early childhood, with onset in the first year occurring in >50% of patients and before 5 years of age in approximately 90% of patients. Although AD can present at any age, other diseases need to be considered in adults with new-onset dermatitis, especially in those without a history of childhood eczema, asthma, or allergic rhinitis (see Table 44.1, Differential Diagnosis). Although in some children, AD may progress to milder forms of eczema, only in approximately one-third will the disease be eliminated altogether. Severity and atopic sensitization are major determinants of prognosis. A US registry of patients with mild-moderate AD showed that it was not until age 20 years that 50% had experienced at least one 6-month period free of symptoms and treatments.[5]

Clinical Features

AD has no pathognomonic skin lesions or unique laboratory parameters; the diagnosis is, therefore, based on the presence of major and associated clinical features (Table 44.2). The principal features include pruritus, a chronically relapsing course, typical morphology and distribution of skin lesions, and a history of atopic disease. Patients usually have dry xerotic skin, and those with mutations of the gene encoding the epidermal barrier protein filaggrin (*FLG*) typically have prominent scaling and hyperlinear palms. Acute AD is characterized by pruritic, erythematous papules associated with excoriations, vesiculations, and serous exudate. Subacute AD is characterized by erythematous, excoriated, scaling papules, whereas chronic AD is characterized by lichenification and fibrotic papules. During infancy, AD involves primarily the face, scalp, and the extensor aspects of the extremities; the diaper region is typically spared, although some infants manifest the flexural involvement typical of older patients (Fig. 44.1).

Complicating Features

Ocular Problems

Atopic keratoconjunctivitis is bilateral, with intense pruritus, burning, tearing, and copious mucoid discharge. It is frequently associated with eyelid dermatitis and chronic blepharitis and may result in visual impairment from corneal scarring. Patients may also develop keratoconus from persistent rubbing of the eyes or anterior subcapsular cataracts.

Hand Dermatitis

Patients with AD may have a nonspecific irritant hand dermatitis aggravated by repeated wetting, especially in an occupational setting.

Infections

Patients with AD have an increased susceptibility to infection or colonization with a variety of organisms.[2] *Staphylococcus aureus* can be cultured from the skin of the majority of patients with

TABLE 44.1 Differential Diagnosis of Atopic Dermatitis

Congenital Disorders

- Netherton syndrome
- Familial keratosis pilaris

Chronic Dermatoses

- Seborrheic dermatitis
- Contact dermatitis (allergic or irritant)
- Nummular eczema
- Psoriasis
- Ichthyoses

Infections and Infestations

- Scabies
- Human immunodeficiency virus (HIV)–associated dermatitis
- Dermatophytosis

Malignancies

- Cutaneous T-cell lymphoma (mycosis fungoides/Sézary syndrome)
- Letterer-Siwe disease

Autoimmune Disorders

- Dermatitis herpetiformis
- Pemphigus foliaceus
- Graft-versus-host disease (GvHD)
- Dermatomyositis

Immunodeficiencies

- Wiskott-Aldrich syndrome (WAS)
- Severe combined immunodeficiency syndrome (SCID)
- Hyperimmunoglobulin E (IgE) syndrome (HIES)
- Dedicator of cytokinesis 8 (DOCK8)–associated immunodeficiency
- Tyrosine kinase 2 (TYK2) deficiency
- Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome

Metabolic Disorders

- Zinc deficiency
- Pyridoxine (vitamin B6) and niacin deficiency
- Multiple carboxylase deficiency
- Phenylketonuria

TABLE 44.2 Clinical Features of Atopic Dermatitis

Major Features

- Pruritus
- Facial and extensor involvement in infants and children
- Flexural lichenification in adults
- Chronic or relapsing dermatitis
- Personal or family history of atopic disease

Minor Features

- Xerosis
- Cutaneous infections
- Nonspecific dermatitis of the hands or feet
- Ichthyosis, palmar hyperlinearity, keratosis pilaris
- Pityriasis alba
- Nipple eczema
- White dermatographism and delayed blanch response
- Anterior subcapsular cataracts
- Elevated serum immunoglobulin E (IgE) levels
- Positive immediate-type allergy skin tests

Modified from Hanifin JM, Rajka G. Diagnostic features of atopic dermatitis. Acta Derm Venereol (Stockh) 1980;92:44–7.

AD. Preferential adherence of this organism in AD may be related to expression of adhesins, such as fibronectin and fibrinogen, in inflamed skin. Recurrent pustulosis has become a significant problem for a number of patients, especially with the emergence of methicillin-resistant *S. aureus* (MRSA) as an important pathogen in AD.

Viral infections in AD include herpes simplex, molluscum contagiosum, and human papillomavirus infections. Patients who have atopic dermatitis with eczema herpeticum (ADEH) have more severe disease, increased body surface area affected, and an increase in biomarkers, including circulating eosinophil counts, serum immunoglobulin E (IgE), thymus and activation-regulated chemokine, and cutaneous T cell–attracting chemokine, compared with patients with AD who do not have a history of EH. Patients with ADEH also have more cutaneous infections caused by *S. aureus* or molluscum contagiosum virus and are more likely to have a history of asthma, as well as food and inhalant allergies. Patients with ADEH have reduced interferon-γ (IFN-γ) production. IFNγ and IFNγR1 SNPs are significantly associated with ADEH and may contribute to an impaired immune response to herpes simplex virus. In addition, genetic variants in IFN-γ regulatory factor 2 (IFN-γR2) have been shown to be associated with ADEH and may contribute to abnormal immune responses to herpes simplex virus.

Superimposed dermatophytosis may contribute to cutaneous inflammation in AD. The opportunistic yeast *Malassezia sympodialis* (previously *Pityrosporum ovale*) has been associated with a predominantly head and neck distribution of AD.

Systemic Complications

A significant number of patients with AD do not outgrow their disease and can have systemic inflammation with increased risk for systemic diseases, including cardiovascular disease,[6] rheumatoid arthritis, and/or inflammatory bowel disease.[7]

Psychosocial Implications

Patients with AD frequently respond to stress or frustration with itching and scratching. Stimulation of the central nervous system (CNS) may intensify cutaneous vasomotor and sweat responses and contribute to the itch–scratch cycle. Scratching can be associated with significant secondary gain or with a strong habitual component. Severe disease can lead to problems with self-esteem and social interactions. Sleep abnormalities are common and can contribute to impaired quality of life of patients and family members, even when the skin disease appears to be in remission.

Differential Diagnosis

A number of diseases can be confused with AD (see Table 44.1). Immunodeficiency with eczematous rash includes immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome. IPEX results from mutations of *FOXP3,* a gene located on the X chromosome that encodes a DNA-binding protein required for development of regulatory T cells (Tregs). Patients may present with enteropathy, type 1 diabetes, thyroiditis, hemolytic anemia, and/or thrombocytopenia. Wiskott-Aldrich syndrome (WAS) is an X-linked recessive disorder characterized by an eczematous rash, associated with thrombocytopenia along with variable abnormalities in humoral and cellular immunity and severe bacterial infections. Hyper-IgE syndrome (HIES) with mutations in the signal transducer and activator of transcription 3 gene (*STAT3*) is an autosomal dominant multisystem disorder characterized by recurrent deep-seated bacterial infections, including cutaneous cold abscesses and pneumonias caused by *S. aureus.* Patients with mutations in the gene encoding dedicator of cytokinesis 8 protein (*DOCK8*) have an immunodeficiency with eczema, recurrent viral infections, including some with CNS involvement, and many have associated food allergies. Patients with tyrosine kinase 2 (TYK2) deficiency can also present with an eczematous rash with high serum IgE and recurrent cutaneous staphylococcal infections. Other diseases to consider in the differential diagnosis of AD include cutaneous T-cell lymphoma, especially in adults with no history of childhood eczema and without other atopic features, human immunodeficiency virus (HIV) infection, and CD (see section on ACD). Contact allergy can also complicate AD, especially in patients whose AD does not respond to or worsens with therapy.

PATHOGENESIS OF ATOPIC DERMATITIS

Genetics

The genetics of AD are complex with key roles played by skin barrier or epidermal differentiation genes and immune response or host defense genes.

KEY CONCEPTS

Pathogenesis of Atopic Dermatitis (AD)

- Patients with AD have abnormalities of skin barrier and immune dysregulation.
- Some patients with AD have decreased filaggrin in the skin based on mutations in the gene encoding filaggrin (*FLG*), copy number variation of *FLG,* or secondary to type 2–mediated cytokine (*e.g.,* IL-4, IL-13) suppression of *FLG.*
- *FLG* mutations are associated with early-onset, severe, persistent AD with increased risk for asthma and allergic sensitization.
- Normal-appearing skin in patients with AD is associated with immune activation and epidermal terminal differentiation abnormalities.
- Patients with AD are predisposed to *Staphylococcus aureus* colonization or infection, and a small subset are prone to eczema herpeticum.
- Patients with an “Asian phenotype” of AD have features of psoriasis with increased T-helper 17 (Th17) and Th22 along with increased Th2 skewing.

Loss-of-function mutations of *FLG* are a major predisposing factor for AD. Patients with *FLG* gene mutations have early-onset, severe, and persistent AD and are at increased risk for developing asthma, as well as food and inhalant allergies.[8] Other skin barrier proteins implicated in AD include loricrin and involucrin, which are both significantly decreased in lesional and nonlesional skin of patients with AD. Candidate gene approaches have also implicated variants in the *SPINK5* gene, and haplotype tagging of SNPs for the claudin-1 gene (*CLDN1*) has revealed associations with AD. These observations have established a key role for impaired skin barrier function in the pathogenesis of AD that allows increased transepidermal water loss and penetration of allergens, antigens, and chemicals from the environment, resulting in cutaneous inflammation. Additional genome-wide significant susceptibility loci identified through the genome-wide association study (GWAS) and immunochip analysis continue to be reported and suggest a role for epidermal barrier function, innate-adaptive immunity, interleukin-1 (IL-1) family signaling, Tregs, the vitamin D pathway, and the nerve growth factor pathway in the pathogenesis of AD.[9] Thus a combination of varied genetic factors may influence a wide range of phenotypes of AD among individuals.

Immune Abnormalities in Atopic Dermatitis

Immunohistology

On the basis of clinical appearance and duration of illness, AD skin can be characterized as nonlesional AD, acute AD lesions (≤3 days after onset), and chronic skin lesions. Nonlesional AD skin is not normal and is characterized by a sparse perivascular T-cell infiltrate, suggesting the presence of minimal inflammation at baseline. Langerhans cells (LCs) also exhibit surface-bound IgE molecules, which have enhanced capacity to present allergen to T cells. In acute lesions, there is epidermal spongiosis with an increased infiltration of activated memory T cells bearing the skin-homing cutaneous lymphocyte-associated antigen (CLA$^+$). Eosinophils, basophils, and neutrophils are rare. Mast cells are seen in various stages of degranulation.

Chronic lichenified AD lesions are characterized by epidermal hyperplasia, prominent hyperkeratosis, and an increased number of dendritic cells (DCs) bearing surface IgE. Macrophages dominate the dermal mononuclear cell infiltrate, but lymphocytes remain prominent. Although intact eosinophils are rarely seen, eosinophil product deposition can be readily identified, suggesting they contribute to allergic skin inflammation.

Immune Pathways in Atopic Dermatitis

AD is associated with a combination of defective innate responses to microbes and altered adaptive responses to environmental allergens (reviewed in references[1,2,10]). A key difference between epidermal keratinocytes found in AD skin, compared with normal skin, is the presence of thymic stromal lymphopoietin (TSLP) and IL-33 in the AD epidermis. TSLP and IL-33 are key cytokines secreted by epithelial cells that induce DCs to drive T-helper 0 (Th0) cells into the Th2-cell differentiation pathway. Nonlesional AD and acute AD skin lesions are predominantly associated with expression of IL-4, IL-5, IL-13, IL-25, and IL-33. These type 2 cytokines are present in all stages of AD and can be secreted by multiple cell types, including innate lymphoid type 2 cells (ILCs), mast cells, and basophils, which are present in AD skin lesions and contribute to substantial redundancy in allergic inflammation. As such, cytokine targeting, as opposed to cell targeting, is considered a more effective approach in the treatment of AD. It is noteworthy that experimental studies demonstrate pretreatment with IL-4 and IL-13 dampens responses to IFNs and IL-17, suggesting that once the early AD lesion is exposed to IL-4 and IL-13, there is a long-lasting persistent effect.

Besides Th2, other cytokine pathways are also activated during the evolution of AD. The IL-22–IL-17 pathway is of particular interest, since it, along with IL-4 and IL-13, can inhibit terminal keratinocyte differentiation, including filaggrin expression. Since DC-derived IL-23 enhances IL-22/IL-17 cell differentiation, all of these cytokines are being closely examined for their potential role in AD. It is interesting that IL-4 and Il-13 can enhance IL-23 production by DCs. Furthermore, blockade of the IL-4 and IL-13 pathway, leading to improvement in AD, is also associated with reduced IL-23 and IL-17 expression in AD skin. When acute AD skin lesions become chronic, there is an increase in Th1 cytokines, such as IFN-γ, which potentiates AD skin inflammation. A recent birth cohort study, however, demonstrated that TSLP could be detected in at-risk infants before onset of AD, suggesting that

FIG 44.1 (A) In patients with irritant contact dermatitis (ICD), exposure to an irritant exerts toxic effects on keratinocytes (KCs), activating innate immunity with release of interleukin (IL)-1α, IL-1β, tumor necrosis factor (TNF)-α, granulocyte macrophage–colony-stimulating factor (GM-CSF), and IL-8 from epidermal keratinocytes. In turn, these cytokines activate Langerhans cells (LCs), dermal dendritic cells (DCs), and endothelial cells, all of which contribute to cellular recruitment to the site of keratinocyte damage. Infiltrating cells include neutrophils, lymphocytes, macrophages, and mast cells, which further promote an inflammatory cascade. (B) In the sensitization phase of allergic contact dermatitis (ACD), similar to ICD, allergens activate innate immunity through keratinocyte release of IL-1α, IL-1β, TNF-α, GM-CSF, IL-8, and IL-18, inducing vasodilation, cellular recruitment, and infiltration. LCs and dermal DCs encounter the allergen and migrate to the draining lymph nodes, where they activate hapten-specific T cells, which include T-helper cell-1 (Th1), Th2, Th17, and regulatory T cells (Tregs). These T cells proliferate and enter the circulation and site of initial exposure, along with mast cells and eosinophils (EOS). On re-encountering the allergen, the elicitation phase occurs, in which the hapten-specific T cells, along with other inflammatory cells, enter the site of exposure and, through release of cytokines and consequent stimulation of keratinocytes, induce an inflammatory cascade. (C) In patients with atopic dermatitis (AD), a disturbed epidermal barrier leads to increased permeation of antigens, which encounter LCs, inflammatory dendritic epidermal cells (IDECs), and dermal DCs, activating Th2 T cells to produce IL-4 and IL-13. DCs then travel to lymph nodes, where they activate effector T cells and induce immunoglobulin E (IgE) class-switching. IL-4 and IL-13 stimulate keratinocytes to produce thymic stromal lymphopoietin (TSLP). TSLP activates OX40 ligand–expressing dermal DCs to induce inflammatory Th2 T cells. Cytokines and chemokines, such as IL-4, IL-5, IL-13, eotaxins, CCL17, CCL18, and CCL22, produced by Th2 T cells and DCs stimulate skin infiltration by DCs, mast cells, and eosinophils. Th2 and Th22 T cells predominate in patients with AD, but Th1 and Th17 T cells also contribute to its pathogenesis. The Th2 and Th22 cytokines (IL-4/IL-13 and IL-22, respectively) have been shown to inhibit terminal differentiation and contribute to the barrier defect in patients with AD. Thus both the barrier defects and immune activation alter the threshold for ICD, ACD, and self-reactivity in patients with AD. MBP, Major basic protein. (Figure adapted from Gittler JK, Krueger JG, Guttman-Yassky E. Atopic dermatitis results in intrinsic and immune abnormalities: implications for contact dermatitis. J Allergy Clin Immunol 2013;131:300–13.)

the TSLP–Th2–ILC2 pathway plays a critical role in initiation of AD.[11]

Epidermal Barrier Dysfunction

The clinically dry skin and increased transepidermal water loss (TEWL) in AD reflects underlying skin barrier dysfunction and loss of natural moisturizing factor that plays an important role in the pathogenesis of AD. However, only a minority of patients have *FLG* null mutations. Other genetic variants in the epidermal differentiation complex (EDC) and tight junctions are even rarer. The majority of patients with AD likely have immune-mediated reduction in epidermal terminal differentiation, which leads to reduced generation of various epidermal structural proteins, filaggrin breakdown products, lipids, and antimicrobial peptides. TSLP, IL-4, and IL-13 are the most potent cytokines downregulating filaggrin expression by keratinocytes.[12] IL-17, IL-22, IL-25, and IL-33 can act synergistically with IL-4 and IL-13 to further downregulate expression of epidermal proteins and lipids. This combination of events, along with activation of proteases and lipases, creates defective epidermal barrier function, alters epidermal acidification, and leads to loss of moisturization in AD, thereby contributing to enhanced allergen and microbial penetration met by the host immune response and clinical appearance of AD.

MANAGEMENT OF ATOPIC DERMATITIS

Recent guidelines address the management of AD.[13,14] Recognition of skin barrier and immune abnormalities suggests the need for barrier repair and maintenance along with antiinflammatory measures.[15]

THERAPEUTIC PRINCIPLES

Atopic Dermatitis (AD)

- Fundamentals of skin care in AD include avoidance of irritants and proven allergens, along with proper skin hydration and use of moisturizers.
- Patients and caregivers have concerns about topical steroids and calcineurin inhibitors and tend to underuse prescribed medications.
- If eczema cannot be cleared and the patients keep relapsing, they may benefit from proactive intermittent antiinflammatory therapy.
- The diagnosis of AD should be reconsidered in patients not responding to conventional therapy, as the differential diagnosis includes a number of immunodeficiencies with eczematous rash.
- Systemic therapies should be reserved for patients with moderate-to-severe AD that does not respond to conventional therapy.

Identification and Elimination of Exacerbating Factors

Irritants

Patients with AD have a lowered threshold of irritant responsiveness. Recognition and avoidance of irritants is integral for successful management of this disease.

Allergens

Identification of clinically relevant allergens involves taking a careful history and doing selective testing, when appropriate. Negative skin tests with proper controls have a high predictive value for ruling out a suspected allergen. Positive skin tests have a lower correlation with clinical symptoms and may reflect sensitization.[16] Patients with severe AD who are avoiding foods based on *in vitro* testing results can tolerate many of the foods previously avoided when they are introduced under supervision. Environmental control measures aimed at reducing dust mite allergen can also improve AD in sensitized patients.

Psychosocial Factors

Recognizing and addressing sleep disturbance in patients is critical in managing a chronic, relapsing disease such as AD. Counseling together with relaxation, behavioral modification, and biofeedback may all be of benefit, especially for patients with habitual scratching.

Patient Education

Patients and caregivers need to be educated regarding the chronic relapsing nature of AD, its natural history, exacerbating factors, and treatment options. Recognizing that normal-appearing skin in patients with AD is, in fact, *not* normal is a difficult concept to understand but has important therapeutic implications. Patients should be counseled about prognosis and receive appropriate vocational counseling.

Hydration

The skin of patients with AD shows enhanced TEWL and lipid abnormalities that result in reduced water-binding capacity, higher TEWL, and decreased water content.[10] Skin hydration by soaking the affected area or bathing and applying an occlusive agent to retain absorbed water can help restore barrier function.[15] Bathing can also remove allergens, reduce *S. aureus* colonization, and act as relaxation therapy.

Moisturizers and Occlusives

Use of moisturizer or occlusive, especially when combined with hydration therapy, helps restore and preserve the skin barrier and can result in decreased need for topical corticosteroids. Twice-daily emollient application has been shown to improve barrier function and protect the skin from *S. aureus* proliferation while preserving microflora biodiversity.[17] Patients with AD have been shown to have a ceramide deficiency of the stratum corneum; barrier repair may be accelerated by increasing the ratio of ceramides, cholesterol, and either the essential fatty acid linoleic acid or the nonessential palmitic or stearic fatty acids.

Corticosteroids

Corticosteroids reduce inflammation and pruritus in acute and chronic AD, acting on multiple resident and infiltrating cells, primarily through suppression of inflammatory genes. Topical corticosteroids have been the mainstay of conventional therapy: when they are appropriately used, side effects are infrequent. Thinning of skin, telangiectasia, bruising, hypopigmentation, acne, striae, and secondary infections may occur. The face, particularly the eyelids, and the intertriginous areas are especially sensitive to these adverse effects. If topical corticosteroids are used on the face, this can lead to perioral dermatitis, characterized by erythema, scaling, and follicular papules and pustules around the mouth, in the alar creases, and sometimes on the upper lateral eyelids.

An important concept with translational applications is the recognition that nonlesional, normal-appearing skin in AD shows evidence of both immunological dysregulation and skin barrier abnormalities.[18] This observation provides a rationale for the use of topical corticosteroids in a proactive manner.[7] If the eczema can be cleared or almost cleared but has a relapsing course, long-term control can be maintained with twice-weekly applications of topical corticosteroid to areas that had previously been involved but now appear normal, with fewer relapses and less need for topical corticosteroids compared with treating eczema in a reactive manner.

In addition to their anti-inflammatory properties, topical corticosteroids can decrease *S. aureus* colonization in patients with AD. Failure to show clinical improvement with topical corticosteroids may be due to inadequate potency or amount of medication used, superinfection, steroid allergy, steroid resistance, or, more commonly, nonadherence with the treatment regimen, emphasizing the need for both education and alternative therapies.

Systemic corticosteroids, including oral prednisone, should be avoided in the management of a chronic disorder such as AD.[13,19] Improvement observed with systemic corticosteroids may be associated with flaring of AD after discontinuation. If a short course of oral corticosteroids is given, topical skin care should be intensified during the taper to suppress rebound flaring of AD.

Topical corticosteroid treatment in patients with AD was recently shown to result in improvements of the AD genomic signature. Cytokine levels (IL-12p40, IL-13, IL-22, CCL17, CCL18, peptidase inhibitor 3 [PI3]/elafin, and S100As) were consistently reduced, with corresponding improvements in epidermal disease markers (keratin 16 and loricrin) in lesional skin from responders. Even low-potency corticosteroids can affect a broad array of immune and barrier responses in patients with AD.

Topical Calcineurin Inhibitors

Tacrolimus ointment (0.03% and 0.1%) and pimecrolimus cream (1%) are nonsteroidal topical calcineurin inhibitors (TCIs) approved for the treatment of AD.[13,14] Both drugs have proven effective, with a good safety profile even when used over extended periods, including in infants treated with pimecrolimus. Treatment with TCIs is not associated with skin atrophy and may also be useful in treating patients with steroid insensitivity. A common side effect with TCIs is burning or stinging sensation of skin. Ongoing surveillance and recent reports have not shown a trend of increased frequency of viral infections or problems with response to childhood vaccinations. Although there is no evidence of a causal link to cancer and the use of TCIs, the US Food and Drug Administration (FDA) issued a "box warning" because of lack of long-term safety data. The labeling states that these drugs are recommended as second-line treatments and that their use in children under the age of 2 years is currently not recommended. However, a review of epidemiological and clinical data concluded that the published data did not demonstrate any causal relationship between TCI use and malignancy or lymphoma risk.

Studies of proactive treatment with tacrolimus ointment in adults and children have shown benefit.[7] A systematic review and meta-analysis of randomized clinical trials comparing TCIs with topical corticosteroids for AD found that both treatment classes showed similar rates of improvement and treatment success.[20]

Antiinfective Therapy

Systemic antibiotic therapy may be necessary when a secondary infection with *S. aureus* is present.[2] Recolonization after a course of anti-staphylococcal therapy occurs rapidly. Maintenance antibiotic therapy should be avoided because it can result in colonization by MRSA. Bleach baths with dilute sodium hypochlorite may reduce skin infections and improve eczema (based on limited data).[13,14]

Patients with disseminated EH require treatment with a systemic antiviral, such as acyclovir.[2] Recurrent cutaneous herpetic infections can be treated with prophylactic oral acyclovir.[21] Superficial dermatophytosis can be treated with topical or, rarely, with systemic antifungals.

Antipruritic Agents

Pruritus is the most common and least tolerated symptom in AD. Mediators other than histamine, including neuropeptides and cytokines, especially IL-31, can contribute to pruritus, and centrally acting agents, such as opioid receptor antagonists, have been shown to be effective against the itch of AD. Treatment with cyclosporine, which results in decreased transcription of a number of proinflammatory cytokines, leads to rapid improvement in pruritus in many AD patients. Monoclonal antibodies (mAbs) against IL-31 and its receptor are undergoing clinical trials in patients with AD,[22] and two phase three trials of a mAb against IL-4 receptor alpha, inhibiting signaling by IL-4 and IL-13 significantly reduced pruritus and enhanced quality of life.[22a] Systemic antihistamines and anxiolytics may be most useful through sedative effects and should be used primarily at bedtime to avoid daytime somnolence. Short-term use of a sedative to allow adequate rest may be appropriate. Treatment with topical antihistamines and topical anesthetics should be avoided because of the potential for allergic sensitization.

RECALCITRANT DISEASE

Hospitalization

Patients who experience erythroderma, appear to have toxicity, or fail on conventional therapies may require hospitalization.[23] Removing the patient from environmental allergens or stressors, intense education, and assurance of adherence with therapy usually result in marked clinical improvement. The patient can also undergo appropriately controlled provocative challenges to identify potential triggering factors.

Wet Wrap Therapy

Wet wrap therapy (WWT), in which a layer of wet clothing or bandages is placed over topical corticosteroid with a dry layer on top, can reduce inflammation and pruritus and acts as a barrier to trauma associated with scratching. WWT can aid epidermal barrier recovery that persists even after this therapy is discontinued, and clinical benefit can be demonstrated after discontinuation. Overuse can result in chilling, maceration of skin, or secondary infection. WWT should be employed for acute exacerbations of AD or for selective use in areas of resistant eczema, rather than as a maintenance treatment. The package inserts for topical calcineurin inhibitors recommend that they should not be used under occlusive dressings.

Systemic Immunosuppressive Agents

Oral cyclosporine has been shown to be effective in placebo-controlled studies in severe AD, although it is not approved for treatment of AD in most countries. A systematic review of randomized controlled trials evaluating systemic immunomodulating treatments for moderate-to-severe AD found that, of 12 different interventions studied in 34 randomized controlled trials, strong recommendations were only possible for the short-term use of cyclosporine.[24] Patients need to be appropriately monitored while on this medication.[19] Other systemic immunosuppressive drugs that have been used to treat severe AD include mycophenolate mofetil (a purine biosynthesis inhibitor), azathioprine (a systemic immunosuppressive agent affecting purine nucleotide synthesis and metabolism), and methotrexate (a folic acid antagonist that interferes with purine and pyrimidine synthesis).[13,19] All of these drugs require careful monitoring of patients for potential serious adverse effects.

Phototherapy and Photochemotherapy

Ultraviolet (UV) light therapy can be a useful treatment for chronic, recalcitrant AD.[19] Potential long-term adverse effects include premature skin aging and cutaneous malignancies. In patients with moderate-to-severe chronic AD treated with narrow-band UVB phototherapy, gene expression and immunohistochemistry studies of both lesional and nonlesional skin showed that Th2, Th22, and Th1 immune pathways were suppressed and that measures of epidermal hyperplasia and differentiation were normalized. Clinical improvement was associated with decrease in Th2/Th22–associated cytokines and chemokines and, importantly, normalized expression of epidermal barrier proteins. UVB phototherapy has also been shown to significantly decrease levels of toxin-producing *S. aureus* on the skin of pediatric patients with AD.

Allergen-Specific Immunotherapy

Allergen-specific immunotherapy (AIT; Chapter 91) has been administered to patients with AD for many years, although there is a paucity of controlled data on this treatment. Based on limited evidence, the updated Practice Parameter for AD states that AIT may be effective for a subset of patients with AD and aeroallergen sensitivity.[13] A Cochrane review of randomized controlled trials of AIT in AD found that the trials were confounded by high loss to follow-up and lack of blinding.[25] The authors were unable to determine by subgroup analyses a particular allergen, age, or level of disease severity where AIT was more successful.

Biologics and Investigational Therapies

Intravenous Gammaglobulin

Because chronic inflammation and T-cell activation appear to play a critical role in the pathogenesis of AD, high-dose intravenous immunoglobulin (IVIG; Chapter 84) could have immunomodulatory effects in this disease. IVIG could also interact directly with infectious organisms or toxins involved in the pathogenesis of AD. IVIG has been shown to contain high concentrations of staphylococcal toxin–specific antibodies that inhibit the *in vitro* activation of T cells by staphylococcal toxins. Treatment of severe refractory AD with IVIG has yielded conflicting results. Studies have not been controlled and have involved small numbers of patients. A systematic review of systemic therapies found that IVIG was not efficacious in the treatment of moderate-to-severe AD.[24]

Omalizumab

Treatment of patients with AD with omalizumab has mainly been reported in case reports and case series, showing both clinical improvement and lack of benefit. A placebo-controlled trial of omalizumab given for 16 weeks did not show significant clinical benefit. No specific markers have been identified that define responders, although a recent study suggested that adult patients with AD that responds to treatment have wild-type *FLG* mutations. In addition, patients receiving omalizumab have been shown to have decreased levels of TSLP, OX40L, thymus and activation-regulated chemokine (TARC), and IL-9 and marked increase in IL-10 compared with placebo.

Rituximab

Rituximab, a chimeric monoclonal anti-CD20 antibody has been given to patients with severe AD, with skin biopsies showing significant improvement in spongiosis and acanthosis and dermal T-cell and B-cell infiltrates decreased as well.[13] Although total serum IgE levels were reduced, allergen-specific IgE levels were not affected. Treatment combining omalizumab and rituximab in patients with severe refractory AD was found to be effective, suggesting that optimal therapy may require use of several biologics.

Dupilumab

Dupilumab is a fully human mAb directed against the IL-4 receptor α subunit that blocks signaling of both IL-4 and IL-13. Results from several randomized, double-blind, placebo-controlled trials involving adults with moderate-to-severe AD showed that treatment with dupilumab resulted in rapid and dose-dependent improvements in clinical indexes, biomarker levels, and disease transcriptome.[22a,26] Of the patients in the dupilumab group, 85% had a 50% reduction in the Eczema Area and Severity Index (EASI) score compared with 35% in the placebo group ($P<0.001$); 40% of patients in the dupilumab group had an investigator's global assessment score of 0–1 (clear or almost clear) compared with 7% in the placebo group ($P<0.001$); and pruritus scores decreased by 55.7% in the dupilumab group versus 15.1% in the placebo group ($P<0.001$). In a combination study, 100% of the patients in the dupilumab group had a 50% improvement in EASI ($P = 0.002$), compared with 50% of those in the placebo group, even though the patients who received dupilumab used less than half the amount of topical steroids compared with those in the placebo group ($P = 0.16$). Adverse events, such as skin infection, occurred more frequently with placebo; nasopharyngitis and headache were the most frequent adverse events with dupilumab. Of note, treatment with dupilumab monotherapy shifted the RNA expression profile of lesional skin to a more nonlesional signature. Dupilumab was well tolerated with no dose-limiting toxicity. Further dose ranging studies have been reported,[27] and studies in adolescents and children are ongoing.

Anti–IL-12/IL-23

Ustekinumab, an mAb used for treatment of psoriasis and psoriatic arthritis, binds to the common p40 subunit of IL-12/IL-23. A recent study of Japanese and Korean patients with AD found overlapping features of both AD and psoriasis.[22] The Asian AD phenotype described presents a blended phenotype, including increased hyperplasia, parakeratosis, higher Th17 activation, and a strong Th2 component. Although these findings need to be reproduced in a larger population of Asian patients, they do suggest that ustekinumab may be of benefit in a subset of patients with similar features.

Other Biologics

A number of other biologics have been evaluated in preliminary studies or are in early development in AD.[22,28] These include anti–IL-13 (lebrikizumab, tralokinumab), anti–IL-22, anti–IL-31, and anti–IL-31-receptor, as well as anti-TSLP and anti–TSLP receptor. New insights into AD phenotypes as well as better understanding of underlying immunopathology will likely lead to improved selection of appropriate patients for more targeted therapies.

Recombinant Human Interferon-γ

Interferon-γ suppresses IgE synthesis and inhibits Th2 cell function. In patients with AD, treatment with subcutaneous recombinant human interferon-γ (rhIFN-γ) resulted in reduced clinical severity and decreased total circulating eosinophil counts.[13] rhIFN-γ may act primarily on the allergic inflammatory response as opposed to IgE synthesis, and a subset of patients treated with rhIFN-γ could respond to individualized titration of their treatment dose. In a case series of pediatric patients with ADEH, IFN-γ and IVIG were thought to be less likely to enhance the cutaneous viral susceptibility of these patients compared with systemic immunosuppressive therapies.[21]

Phosphodiesterase-4 Inhibitors

Apremilast, an oral phosphodiesterase-4 inhibitor approved for the treatment of psoriasis, was shown in a pilot study in adults with AD to reduce pruritus and improve the Dermatology Quality of Life Index (DLQI) and EASI scores.[29] Gene ontological analyses comparing baseline samples with samples obtained during treatment revealed alterations in immune response pathways, especially those related to cyclic adenosine monophosphate (cAMP)–mediated signaling.

Crisaborole is a benzoxaborole phosphodiesterase 4 (PDE4) inhibitor, which has been approved by the FDA as a 2% topical ointment in children and adults with mild to moderate AD.[30] The unique configuration of boron within the crisaborole molecule enables selective targeting and inhibition of PDE4, increasing cAMP levels and reducing inflammation. In addition, the boron molecule allowed for synthesis of a low-molecular-weight compound (251 daltons), thereby facilitating penetration of crisaborole through human skin. *In vitro* experiments have shown that crisaborole inhibits cytokine production by peripheral blood mononuclear cells similar to other PDE4 inhibitors and distinct from corticosteroids. Randomized controlled clinical trials have shown the efficacy and safety of crisaborole topical ointment 2% in children, adolescents, and adults with mild to moderate AD.

Probiotics

Clinical trials in patients with AD show varying results. A meta-analysis of randomized controlled trials that attempted to overcome some of the limitations of prior reviews found a reduction of approximately 20% in the incidence of AD and IgE-associated AD in infants and children with the use of probiotics. Although these results are encouraging, the use of probiotics for the prevention of AD remains investigational.

PREVENTION

Two preliminary studies have suggested that emollient therapy started in early infancy in at-risk neonates can reduce the incidence of AD.[31,32] Both studies were of relatively short-term duration without follow-up off emollient therapy. It is noteworthy that infants at risk for AD at 1 year of age could be identified as early as day 2 of life by TEWL measurement, independent of parental atopy or *FLG* mutation status.[33]

CONTACT DERMATITIS

CD is a skin disorder caused by contact with an exogenous substance that elicits an allergic and/or irritant response. The vast majority of cases of contact-induced skin reactions are attributable to CD. However, there are other less-well-defined contact reactions, including contact urticaria, contact urticaria syndrome, and protein contact dermatitis. ACD affects approximately 7% of the general population, 13.3–24.5% of pediatric patients,[34] and 33–64% of the elderly population. CD was associated with more than 10.6 million physician office visits, with annual direct costs estimated at \$1.6 billion and indirect costs at \$566 million as a result of loss of work time, school time, and productivity.[35] Numerous studies have reported an increased frequency of ACD in patients with AD,[36] likely as a result of the increased exposure to products and chemicals used to treat AD, the barrier defect, and immunological changes in AD, which predispose a patient to both ICD and ACD.[37]

PATHOGENESIS OF ALLERGIC CONTACT DERMATITIS

The Genes

ACD is a multifactorial condition in which genetic background plays an important part, as shown by twin and family studies. An association has been demonstrated between loss of function mutations R501x and 2282del4 in the filaggrin (*FLG*) gene and contact sensitization against nickel II-sulfate, combined with an intolerance to fashion jewelry but not with other contact allergens.[38] *FLG* mutations have further been shown to lower the age of onset of nickel sensitization.[39] Thus FLG defects may be a risk factor for contact sensitization to allergens.

The Allergens

Most contact allergens are *haptens,* that is, simple chemicals that bind to carrier proteins present in skin to form a complete antigen (Chapter 6). To be allergenic, the chemical must be able to penetrate the principal barrier in skin (stratum corneum) and reach the living cells of the epidermis. Only molecules with molecular mass of <500 daltons (Da) are capable of penetrating the stratum corneum. Lipid solubility promotes transit through the stratum corneum. Thus most contact allergens are small, lipophilic molecules. Once in the epidermis, the nature of the protein carrier for the hapten is very important because if the contact sensitizer is complexed to nonimmunogenic carriers, this may induce tolerance rather than sensitization.[38]

The Immune Response

The immune response of ACD requires completion of both an afferent (sensitization) and an efferent (elicitation) phase.

In the afferent limb, the hapten enters the epidermis and activates keratinocytes to release inflammatory cytokines and chemokines, including tumor necrosis factor (TNF)-α, granulocyte macrophage–colony-stimulating factor (GM-CSF), IL-1α, IL-1β, IL-8, IL-10, IL18, and macrophage inflammatory protein-2 (MIP-2). The activation of LCs, other DCs, and endothelial cells can lead to recruitment of even more DCs at the site of antigen contact. The release of IL-1β by epidermal LCs promotes their egress from the epidermis. LCs process the antigen while migrating to regional lymph nodes, where they present it to naïve T cells. This phase is influenced by multiple factors. Defects in the integrity of the stratum corneum allow greater penetration of allergen and increase the chances of activating antigen-presenting cells (APCs) in skin. The availability and viability of APCs in skin, as well as the presence or absence of cytokines produced by keratinocytes, can promote or hinder APC–T-cell engagement.

In the draining lymph nodes, LCs present the peptides to T cells and activate CD4 and CD8 antigen-specific T cells. An important property of LCs and DCs is their ability to present exogenous antigens on both major histocompatibility complex (MHC) class I and class II molecules. This cross-priming leads to the activation of both CD4 and CD8 hapten-specific T cells. Although classic delayed-type hypersensitivity reactions are mediated primarily by CD4 cells, CD to haptens is mediated primarily by CD8 cells with a Th1-type cytokine profile. LCs activate hapten-specific T cells, which include Th1, Th2, Th17, and Treg subsets.[40] This preexisting mix of T-cell subtypes specific for the antigen influence the outcome of this process. The higher the frequency of cells of an effector subtype, the higher the likelihood that dermatitis will result, whereas a higher frequency of cells of a regulatory subtype may limit or prevent the development of dermatitis.

The efferent phase of ACD occurs on subsequent contact of skin with the hapten. Antigen-specific memory T cells and other inflammatory cells leave vessels and enter skin through sequential activation of a number of adhesion molecules by cytokines. Memory T cells constitutively express CLA. E-selectin, the ligand for CLA, is induced on vascular endothelium by inflammatory mediators, such as IL-1 and TNF-α. This interaction causes memory T cells to slow down and roll along the endothelial surface as a prelude to migration to sites of inflammation. Firm adhesion and migration of leukocytes to the endothelium are mediated by T-cell very late antigen-4 (VLA-4)/leukocyte function–associated antigen-1 (LFA-1) and endothelial cell vascular cell adhesion molecule-1 (VCAM-1)/intercellular adhesion molecule 1 (ICAM-1), respectively (Chapter 11). Subsequently, LFA-1β T cells migrate toward ICAM-1β epidermal cells.

Mast cells can also participate in the elicitation phase. In mice, mast cells can be activated by a T-cell–derived antigen-binding factor that induces release of serotonin, producing swelling 2 hours after challenge. In addition, mast cells contain preformed TNF-α, which may regulate the adhesion molecules involved in the early recruitment of Th cells. The net result is an influx of sensitized T cells homing to the hapten-provoked skin site, releasing their inflammatory mediators, IL-2 and IFN-γ, and this results in an enhanced immune response through activation and recruitment of more inflammatory cells, producing spongiosis and the inflammatory dermal infiltrate characteristic of ACD.

Although Th1 cells have been classically considered the primary effector cells of ACD (responses to haptens, such as nickel, were dominated by IFN-γ–producing cells), recent studies have

KEY CONCEPTS

Pathogenesis of Contact Dermatitis

- Allergic contact dermatitis (ACD) is a delayed-type, T cell–mediated response with an afferent limb or sensitization phase and an efferent or elicitation phase.
- Irritant contact dermatitis (ICD) is caused by irritants exerting toxic effects on keratinocytes, causing a direct activation of the innate immune system through hyperproduction of cytokines and chemokines and inducing an inflammatory skin reaction.
- Patients with ICD are more susceptible to the development of ACD, indicating that the activation of innate immunity by irritants likely reduces the threshold for development of ACD.
- There is an increased frequency of ACD in patients with AD likely because of the disturbed skin barrier allowing increased allergen penetration on an already amplified adaptive response in AD.
- Although ACD, ICD, and AD are independently defined diseases, they frequently interact and coexist.

indicated that Th2 cells also participate in the development of contact hypersensitivity.[41]

Recently, both murine models and human studies have suggested the potential role of Th17 cells in the immunopathogenesis of ACD. Increased levels of cytokines favoring a Th17 response (*i.e.,* IL-6)[42] and allergen-specific IL-17–producing T cells were found in sensitized mice. In addition, IL-17–deficient mice showed decreased secretion of cytokines and chemokines, diminished hapten-specific CD4 T-cell responses, and reduced ear swelling. In patients with ACD, Th17-associated mediators, such as IL-17A, IL-17F, IL-22, IL-23, chemokine receptor 6 (CCR6), IL-22 receptor, and the Th17 transcription factor retinoic acid–related orphan receptor γ, were shown to be produced by nickel-specific T cells and were upregulated in ACD lesional skin and positive patch test biopsy specimens.[43] Nickel exposure was reported to induce production of IL-23 by keratinocytes, promoting a Th17-mediated response, as detected by the presence of IL-17–producing T cells in peripheral blood from patients with nickel allergy.[44] The role of IL-17 in ACD lesions includes induction of keratinocyte release of cytokines and chemokines (*i.e.,* IL-8 and IL-6) and promotion of T cell–induced apoptosis of keratinocytes. The significance of IL-17 in ACD is emphasized by the correlation between the increase in IL-17–producing cells with the clinical manifestations of ACD, as well as by their significant percentage (20%) among skin-infiltrating CD4 and CD8 T cells in contrast to their minor representation (only 1.5%) in the regional lymph nodes of allergen-primed mice.[43]

A particular role for IL-22 (produced by Th22 and Th17 T cells)[45] has been suggested in ACD. Significantly higher levels of IL-22 were detected in the serum of patients with ACD to nickel compared with those seen in control subjects. IL-22 cytokine levels have also been shown to be upregulated in inflamed skin of patients challenged with nickel allergy,[44] although its specific contribution to ACD reactions is not yet known.

The skin of patients with AD is at increased risk for the development of ACD, and this may be attributed to multiple factors. First, AD skin is exposed to chemicals used to treat AD, including moisturizers, topical corticosteroids, and TCIs. Second, the disturbed barrier system allows increased permeation of allergens. Third, AD skin has a heightened immunological status with existing activation of innate immunity, increased access of surface antigens to LCs, and selective upregulation of the Th2 adaptive immune response. In patients with AD, cutaneous contact with irritants and allergens leads to amplification of innate immunity and enhanced adaptive immune responses, including Th2 and Th17 in patients with acute AD and Th22 and Th1 in patients with chronic disease. Just as innate immune activation stimulated by an irritant permits a lower threshold of ACD elicitation, the amplified adaptive responses in lesional and nonlesional skin promote increased expression of ACD and ICD in patients with AD.

PATHOGENESIS OF IRRITANT CONTACT DERMATITIS

ICD accounts for 80% of cases of CD. The clinical presentation of ICD is usually restricted to skin that is directly in contact with the offending agent, with little or no extension beyond the site of contact. The inflammatory response is dose- and time-dependent. Any impairment to the epidermal barrier layer (*e.g.,* fissuring, overhydration) renders skin more susceptible to an irritant effect. Contact with agents, such as detergents, solvents, alcohol, creams, lotions, ointments and powders, and environmental factors, such as wetting, drying, perspiration, and temperature extremes, can abrade or irritate skin. After exposure to skin irritants, perturbation of the skin barrier and disorganization of the lipid bilayers with lamellar body lipid extrusion in the epidermis[46] is seen, with an associated increase in TEWL.

Irritants cause direct activation of the innate immune system through hyperproduction of cytokines and chemokines, such as IL-1α, IL-1β, IL-6, IL-8, and TNF-α, which further induce a cytokine cascade and inflammatory reaction with infiltration of inflammatory cells. Epidermal keratinocytes have been identified as key effector cells in the initiation and propagation of contact irritancy. Keratinocytes can release both preformed and newly synthesized cytokines, and can upregulate MHC class II molecules and induce adhesion molecules in response to irritants.[40] These mediators can cause direct tissue damage, activating LCs, dermal DCs, and endothelial cells, which contribute to further cellular recruitment, including neutrophils, lymphocytes, macrophages, and mast cells, which also contribute to the inflammatory cascade. The "final" cellular damage results from inflammatory mediators released by activated nonsensitized T cells.

Application of sodium lauryl sulfate (SLS) exerts direct toxic effects on keratinocytes (an experimental model of ICD) and has been demonstrated to induce LC mobilization and consequent migration to the draining lymph nodes. Other irritants have been shown to cause direct activation of the innate immune system through a set of membranous and intercellular receptors called Toll-like receptor 7 (TLR-7) and nucleotide-binding oligomerization domain (NOD)–like receptors (NLRs) that activate the inflammasome and nuclear factor-κB (NF-κB) pathways, inducing release of many cytokines and chemokines.

Although few immunohistopathological differences have been noted between ICD and ACD, ICD does not require prior sensitization, and immunological memory is not involved. The cellular infiltrate includes CD4 T cells with a Th1-type profile. Irritant reactions predispose to allergic reactions, making patients with ICD more susceptible to the development of ACD. Animal models in which skin was preirritated with 5% SLS showed an increase in skin sensitization rate to paraphenylenediamine from 38% to 78%[47] and enhanced T-cell proliferative responses to 2,4-dinitrochlorobenzene (DNCB). The DNCB-primed ICD reaction conditioned the development and severity of the ACD response. Similarly, in human studies, when patch test sites were pretreated with SLS, the threshold elicitation concentrations of contact allergens, such as cobalt, nickel, and colophony, were significantly decreased, indicating that the activation of innate immunity by irritants likely reduces the threshold for the development of ACD.

In summary, although ACD, ICD, and AD are independently defined diseases, they interact and frequently occur in combination. In patients with AD, if the activation of an innate immune response is preceded by exposure to irritants and allergens, there is altered permeation of contact allergens, which are introduced into an already activated innate immune system, resulting in amplification of innate immunity and enhanced adaptive immune responses. The amplified adaptive responses in AD promote increased ACD and ICD. Conversely, the innate immune activation stimulated by an irritant permits a lower threshold of ACD elicitation (Fig. 44.2).

CLINICAL MANIFESTATIONS OF CONTACT DERMATITIS

The clinical and histological findings of ACD are characteristic, but not diagnostic. ACD should be suspected in patients with

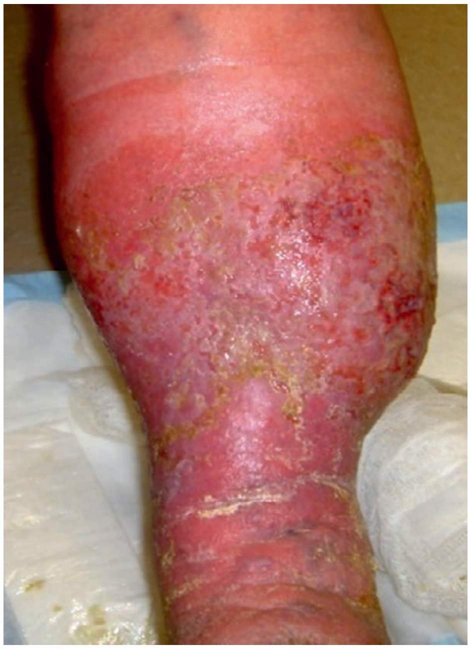

FIG 44.2 Acute allergic contact dermatitis.

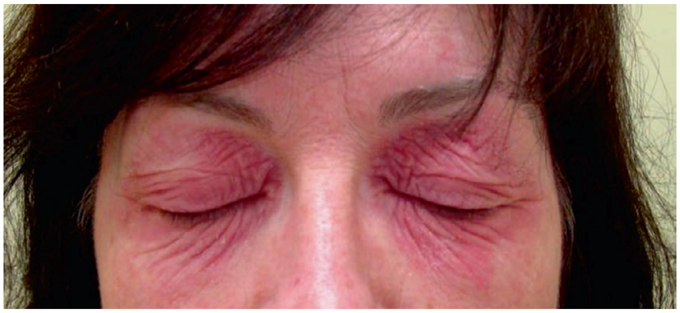

FIG 44.3 Allergic contact dermatitis of the eyelid.

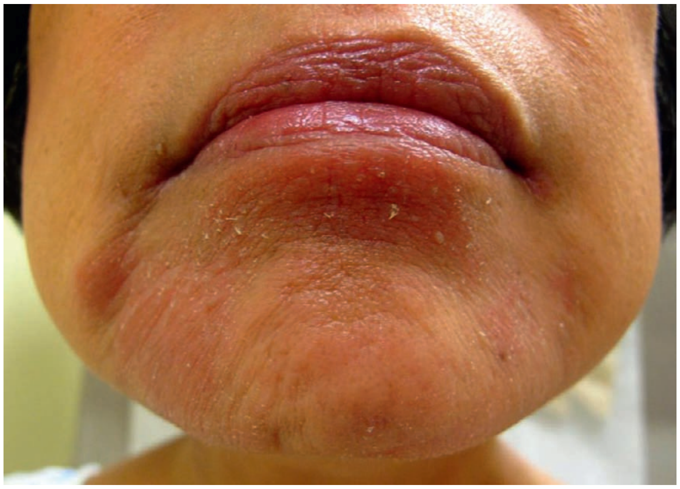

FIG 44.4 Allergic contact dermatitis of the face caused by fragrance.

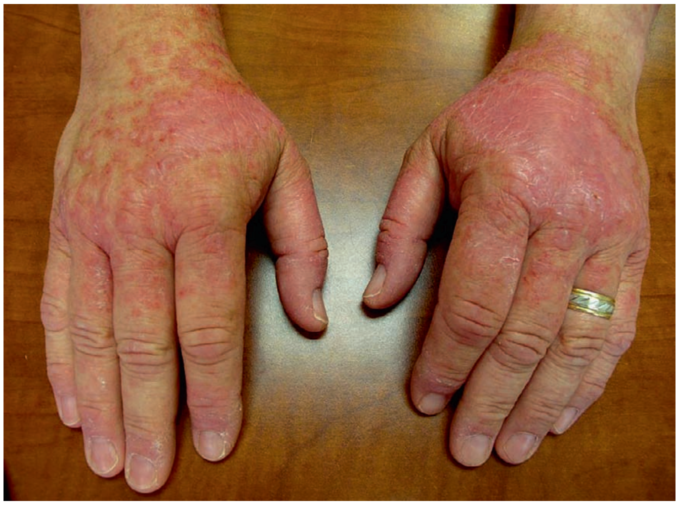

FIG 44.5 Allergic contact dermatitis of the hand caused by rubber accelerators.

acute and chronic eczematous or noneczematous dermatitis and is diagnosed on the basis of the clinical appearance of the lesions, the distribution of the dermatitis, the presence of pruritus, and the absence of other etiologies. Acute CD is characterized by erythematous papules, vesicles, oozing, and crusted lesions (Fig. 44.3). Recurrence and persistence of the dermatitis may lead to subacute and chronic lesions. Subacute CD manifests as erythema, scaling, fissuring, or a parched, scalded appearance and chronic inflammation may have more skin thickening, hardening, scaling, fissuring, and lichenification.

Although the location of the dermatitis serves as an important clue to the source of the offending chemical, multiple factors contribute to the distribution of ACD. Spread from the principal site of exposure can involve distant sites, either by inadvertent contact or by autosensitization. Areas of the scalp, palms, and soles have thicker skin, whereas the eyelid, face, and genital areas have thinner skin that is more sensitive to contact allergens (Figs. 44.4 and 44.5). A geographical approach can be very helpful in identifying the causal allergen, but dermatitis with scattered generalized distribution, which lacks the characteristic distribution that gives a clue as to the possible etiology of ACD, is actually the most common pattern of dermatitis in both children and adults, as reported by the North American Contact Dermatitis Group in 2013, followed by hands and then the face.[48] Systemic contact dermatitis (SCD), specifically the "baboon syndrome," is a diffuse eruption involving flexural and intertriginous areas following oral, intravenous, or transcutaneous exposure to the allergen in a contact-sensitized individual. The most common causes of SCD are *(i)* metals, such as mercury, nickel, and gold; *(ii)* medications, including aminoglycoside antibacterials, topical corticosteroids, and aminophylline; and *(iii)* plants and herbal products, including Compositae and Anacardiaceae families and Balsam of Peru (also known as *Myroxylon pereirae* resin).

Histologically, CD demonstrates intercellular edema of the epidermis (spongiosis) with varying degrees of acanthosis (thickening of the epidermal stratum basale and stratum spinosum) and superficial perivascular, lymphohistiocytic infiltrates. It is often difficult to distinguish ACD (Fig. 44.5) from ICD (Fig. 44.6) on the basis of physical examination or histological findings.

MANAGEMENT OF ALLERGIC CONTACT DERMATITIS

The management of ACD includes identification of the allergen, avoidance, pharmacological intervention, and prevention.

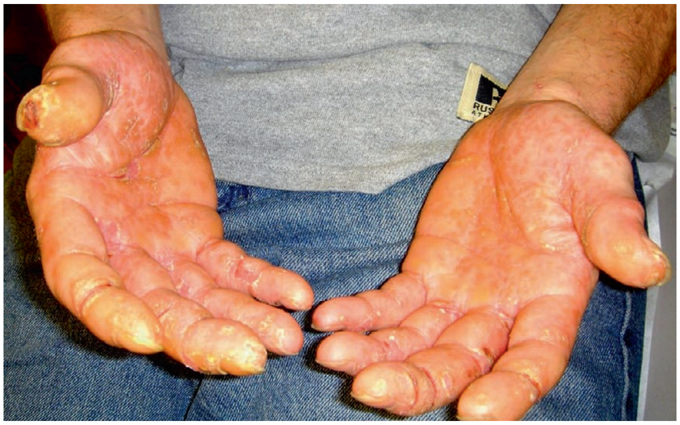

FIG 44.6 Irritant contact dermatitis.

THERAPEUTIC PRINCIPLES

Contact Dermatitis

- Patch testing is the procedure of choice to confirm the diagnosis of allergic contact dermatitis (ACD) and to identify offending contact allergens.
- The interpretation of patch tests requires both experience and judgment on its relevance.
- Once identified, the key to management of ACD is prevention by avoiding substances containing the allergens or irritants that have been identified.
- Medical treatments such as topical and/or systemic corticosteroids can be used to relieve ongoing dermatitis.

Identification of the Allergen

The most widely acceptable and available method for confirming the diagnosis of ACD is patch testing. Nickel remains the most common contact sensitizer and is more common in women than in men, likely because of greater exposure to nickel in jewelry and body piercing practices. In cosmetic products, fragrances, preservatives, and emulsifiers are the most common causative allergens. In addition, paraphenylenediamine (in hair dye), cocamidopropyl betaine (in shampoos and soaps), and medications (*e.g.*, neomycin, benzocaine, corticosteroids) are commonly reported allergens in personal hygiene and medical products. The results of patch tests must be interpreted in the context of the patient's experience; exposure and relevance should be established.[49]

Allergen Avoidance

Once the allergen or irritant has been identified, avoiding further contact with the offending agent would provide improvement of the dermatitis. This requires extensive patient education on what they are allergic to, including synonyms and cross-reactivity, products they must avoid, and, most importantly, products that may be safe for them to use. The dimethylglyoxime test (nickel spot test) and the cobalt spot test (based on disodium-1-nitroso-2-naphthol-3,6-disulfonate) can be used to detect nickel or cobalt released from metal objects and dermal exposure, thus aiding in avoidance of contact in sensitized patients. Use of appropriate skin protection (*i.e.*, gloves) may help with avoidance of exposure, especially in the occupational setting.[50]

Symptomatic Therapy

In addition to avoidance of exposure, appropriate adjunct medical treatment can be prescribed. First-line therapy is with topical corticosteroids, and second-line treatment includes phototherapy, oral retinoids, and immunosuppressant agents. The age of the patient and the severity, location, and acuteness of the dermatitis affect the selection of topical corticosteroids, which may be sufficient for localized lesions. Patients with dermatitis that is acute, extensive (particularly if involving >10% of total body surface), or severe may benefit from systemic therapy.

Contact sensitization to the corticosteroid itself, the vehicle, or other ingredients in the topical corticosteroid should be suspected if symptoms worsen, initially improve but then worsen with continued treatment, or do not respond to treatment at all. Several topical T-cell selective inhibitors (tacrolimus and pimecrolimus) have been used successfully in the treatment of AD, but their efficacy in ACD or ICD has not been established.[51] Other treatments, including cyclosporine, azathioprine, oral retinoids, and phototherapy, have been used for steroid-resistant ACD, such as chronic hand dermatitis.

PERSPECTIVES IN ATOPIC DERMATITIS AND ALLERGIC CONTACT DERMATITIS

Looking into the future, as we define the immune pathways that cause AD, novel biologicals currently in clinical trials may provide more targeted therapy in AD.

ON THE HORIZON

- Novel biologicals currently in clinical trials may provide more targeted therapy in atopic dermatitis (AD).
- Characterization of unique clinical phenotypes of AD may lead to a better understanding of AD pathophysiology and a precision-medicine approach to treatment.
- Identification of "at risk" patients will facilitate preventative strategies.
- A large number of chemicals are in everyday usage: new, rare, and emerging allergens should be considered in the assessment of suspected ACD. Patch testing to these allergens has yet to be standardized and irritant and elicitation concentration to patch testing determined.
- Data about contact allergen sensitization in children with AD are limited and are continually expanding. Frequency and patterns of CD in children with AD and results of patch testing have yet to be determined.

Identification of the endotypes involved in the pathogenesis of unique clinical phenotypes of AD will be required for a precision-medicine approach to treatment. In the absence of a low-cost cure for AD, biomarkers to identify "at-risk" patients could facilitate preventative strategies.

In the area of ACD, a large number of chemicals are being evaluated for their role, and new, rare, and emerging allergens should be considered in the assessment of suspected ACD. Patch testing to these allergens has yet to be standardized; irritant and elicitation concentrations to patch testing need to be determined. Data about contact allergen sensitization in children with AD are limited but are continually expanding. Frequency and patterns of CD in children with AD and the results of patch testing have yet to be determined.

MULTIPLE-CHOICE QUESTIONS

1. Immunodeficiencies with eczematous rash that may be misdiagnosed as atopic dermatitis include all of the following EXCEPT:
   A. Wiskott-Aldrich syndrome (WAS)
   B. Properdin deficiency
   C. Immunodeficiency with mutations in dedicator of cytokinesis 8 (*DOCK8*)
   D. Immune dysregulation, polyendocrinopathy, enteropathy X-linked (IPEX) syndrome

2. The TRUE statement regarding filaggrin is:
   A. Mutations in the gene encoding filaggrin (*FLG*) occur only in patients of European Caucasian descent.
   B. Filaggrin is an enzyme that regulates breakdown of the epidermal barrier.
   C. T-helper 2 (Th2) cytokines interleukin-4 (IL-4) and IL-13 can downregulate *FLG* gene expression.
   D. Abnormal filaggrin expression in bronchial epithelium leads to increased risk of asthma.

3. Which of the following is a TRUE statement regarding atopic dermatitis?
   A. Downregulation of a number of antimicrobial peptide genes caused by local upregulation of Th2-type cytokines could explain the increased susceptibility of patients with atopic dermatitis (AD) to cutaneous infections.
   B. Serum levels of thymus and activation-regulated chemokine (TARC) rise with successful treatment.
   C. Patients whose AD has been in remission for >5 years are no longer at increased risk for eczema vaccinatum from smallpox vaccine.
   D. Langerhans cells are the primary source of antimicrobial peptides in skin.

4. Which of the following is the MOST common contact allergen?
   A. Neomycin
   B. Nickel
   C. Paraphenylenediamine
   D. Cocamidopropyl betaine

Food Allergy

J. Andrew Bird, Stacie Jones, Wesley Burks

Adverse reactions to foods may be mediated by immunological mechanisms (food allergy) and nonimmunological mechanisms (food intolerance). Immune-mediated reactions to foods most commonly involve immunoglobulin E (IgE), an antibody that binds to mast cells and basophils. Upon exposure to allergen, they release inflammatory mediators, such as histamine, prostaglandins, and leukotrienes, resulting in symptoms ranging from localized oral itching to anaphylaxis, a potentially fatal systemic reaction. Non–IgE-mediated immune reactions to foods include such diseases as celiac disease and food protein–induced enterocolitis syndrome (FPIES), while other diseases, such as eosinophilic esophagitis (EoE) and eosinophilic gastroenteritis (EGE), involve both IgE-mediated and non–IgE-mediated mechanisms. Food allergy has a significant negative effect on quality of life, and the burden on the health system amounts to approximately $25 billion US dollars annually.[1] Current management of food allergy relies on avoidance, but ongoing research into treatment for food allergy should provide options for the majority of affected persons in the near future. This chapter will review the basics of food allergy diagnosis, management, and natural history, with a specific focus on IgE-mediated food allergies.

KEY CONCEPTS

Common Characteristics of Most Frequently Encountered Food Allergens

A relatively small molecular weight (<70 kDa)
Abundant source of the relevant allergen
Glycosylation residues
Water solubility
Most are resistant to heat and digestion

PREVALENCE

The true prevalence of food allergy is difficult to establish. This is probably because *(i)* studies have focused on only the most common food allergens; *(ii)* the incidence and prevalence of food allergy may be increasing and changing with time, with studies showing an increasing prevalence over the past 10–20 years; and *(iii)* studies of prevalence are difficult to compare because of inconsistencies and deficiencies in study design.[2] Best estimates suggest a self-reported prevalence of food allergy of 12% and 13% for children and adults, respectively, with confirmed food allergy in approximately 3% of adults and children when assessed by double-blind placebo-controlled food challenge.[3] The most common foods to trigger reactions in children are cow's milk (2.5%), hen's egg (1.3%), peanut (0.8%), wheat (~0.4%), soy (~0.4%), tree nuts (*e.g.*, cashew and walnut) (0.2%), fish (0.1%), and shellfish (0.1%). Prevalent allergens vary in different cultural groups, with milk, egg, peanut, and tree nut allergens topping the lists in the Americas, Australia, and Western Europe, whereas fish and shellfish allergies are more common in Asia.[4] Most food allergies are typically outgrown; however, allergies to some foods, such as peanut, tree nuts, fish, and shellfish, are often more persistent, and these are the food allergens most commonly reported in adults. Food allergy commonly co-occurs with other atopic diseases, such as atopic dermatitis (AD), asthma, and allergic rhinitis.[5]

SPECTRUM OF DISEASE

IgE-Mediated Food Allergies

Immediate reactions to foods compose the largest proportion of food-induced allergic diseases. IgE-mediated food allergy occurs when allergenic proteins cross-link allergen-specific IgE bound to mast cells or basophils, leading to release of histamine and other inflammatory mediators. Symptoms of IgE-mediated food allergy usually occur within minutes after ingestion of the provoking food allergen, and do not start >2 hours later except in very rare circumstances (*e.g.*, delayed anaphylaxis related to red meat ingestion).

Symptoms may be severe (*e.g.*, anaphylaxis) or localized (*e.g.*,. pollen-food allergy syndrome). Characteristic signs of an immediate allergic reaction manifest through skin and subcutaneous tissues (*e.g.*, urticaria and/or angioedema), the respiratory system (*e.g.*, bronchospasm), the gastrointestinal system (*e.g.*, vomiting and/or diarrhea), and/or the cardiovascular system (*e.g.*, increased vascular permeability leading to hypotension). Anaphylaxis is the most severe symptom of food allergy and may result in death (Chapter 42).

Pollen-food allergy syndrome (PFAS, or oral allergy syndrome) symptoms are restricted to the lips, throat, and mouth and are most commonly elicited due to fruit and vegetable proteins cross-reacting with antibodies against pollen proteins in individuals with pollen allergy. Affected individuals will typically complain of pruritus and/or tingling of the lips, tongue, roof of the mouth, and throat with or without swelling. PFAS reactions are unlikely to progress to a systemic reaction.

More than 170 foods have been reported to be allergenic, but most of the food-induced allergic reactions are caused by eight food groups.[5] Cow's milk, hen's egg, and peanut are the most commonly identified food allergens in the United States, followed by tree nuts, wheat, soy, fish, and crustacean shellfish.[6] There is variability across the world and cultural groups with regard to which allergens are the most common, but cows' milk and hen's

TABLE 45.1 Food Allergens by Family

Food Allergen Family	Foods Containing Allergen	Description
Tropomyosins	Crustacean shellfish (*e.g.,* shrimp, lobster, crab), mollusks (*e.g.,* oyster, scallop, squid)	Invertebrate tropomyosins are a family of muscle proteins that share homology across invertebrate species and therefore may act as panallergens. They do not share homology with vertebrate tropomyosins. They are generally heat stable and highly cross-reactive.
Parvalbumins/EF-hand proteins	Vertebrate fish and frogs	Muscle proteins that possess a calcium-binding domain referred to as an EF-hand motif. This is the second-largest family of allergens, and these allergens are considered highly cross-reactive panallergens.
Casein	Mammalian milk	Function to bind calcium and stabilize it in micellar form. There is high sequence homology between cow's milk and other mammalian milks, such as goat's milk and sheep's milk. Other animal milks such as human milk, horse's milk, donkey's milk, and camel's milk have caseins with approximately 60% homology, which may account for less allergenicity than seen with cow's milk.
Prolamin superfamily	Seeds, tree nuts, legumes (including peanut), fruits, vegetables, wheat, corn, rice	This family contains the highest number of plant food allergens and is characterized by rich disulfide bonds and a core of eight conserved cysteine residues, providing stability and resistance to digestion. Families within this superfamily include 2S albumin seed storage proteins, nonspecific lipid transfer proteins, and α-amylase/trypsin inhibitors.
Cupin superfamily	Legumes, nuts, seeds	A large and functionally diverse superfamily of proteins termed seed storage globulins that share a β-barrel structural core domain. Seed storage globulins may be grouped into two families: vicilins and legumins.
Bet v 1 superfamily	Apple, pear, stone fruits, celery, carrot, soybean, peanut	Bet v 1 is the major birch pollen allergen and is a member of the pathogenesis-related protein 10 family within this superfamily. Symptoms of Bet v 1 hypersensitivity typically present with pollen food allergy syndrome (also known as oral allergy syndrome), which is caused by IgE cross-reactivity between Bet v 1 and homologous allergens from plant foods.

From Sampson HA, Aceves S, Bock SA, et al. Food allergy: a practice parameter update-2014. J Allergy Clin Immunol 2014;134:1016–25 e1043.

egg tend to be the most common allergens across varying geographical locations and cultural groups.[7] The most common food and plant allergens are listed in Table 45.1.

Because of protein similarities between allergens, cross-reactivity occurs. Patients allergic to certain foods should be counseled to avoid cross-reactive food proteins. It is common to find cross-reactivity among tree nuts; in particular, cashew and pistachio share common allergen binding sites, as do walnut and pecan. Between 25% and 50% of patients with peanut allergy are also allergic to tree nuts, with particular cross-reactivity noted between peanut allergens and tree nut allergens in almond, walnut, pecan, hazelnut, and Brazil nut. Tropomyosins found in crustacean shellfish are a panallergen,[5] and approximately 75% of individuals allergic to one crustacean (*e.g.,* shrimp) are likely to also react to another crustacean (*e.g.,* lobster and/or crab).[8] Parvalbumins found in vertebrate fish are commonly cross-reactive on testing, but clinical relevance of cross-reactivity varies. Studies have shown that an individual allergic to one fish species has approximately a 50% likelihood of reacting to another species of fish.

Although most reactions occur immediately after ingestion, some individuals may experience delayed anaphylaxis following ingestion of mammalian meat.[5] Delayed allergy to mammalian meats has been linked to the production of IgE to α-gal in susceptible subjects. α-Gal is an immunogenic oligosaccharide, and sensitization is believed to occur via a tick bite. Symptoms of urticaria, angioedema, and anaphylaxis can occur 3–6 hours after eating beef, pork, lamb, and venison. The mechanism(s) underlying the delayed reaction is poorly understood.

Mixed IgE/Non-IgE– and Non–IgE-Mediated Food Allergies

Delayed gastrointestinal (GI) reactions to foods include such diseases as EoE, EGE, FPIES, and eosinophilic proctocolitis (Chapter 46). The most common food proteins involved in these diseases include milk, egg, wheat, and soy. Celiac disease is a non–IgE-mediated food allergy triggered by ingestion of gluten-containing grains (*e.g.,* wheat, barley, and rye). Human leukocyte antigen (HLA) DQ2- or DQ8-restricted CD4 T cells, which recognize gluten selectively in affected persons, are critical to the pathogenesis of celiac disease.

EoE is a clinicopathological diagnosis, based on symptoms of esophageal dysfunction (including dysphagia, vomiting, feeding disorders, and abdominal pain) together with pathological findings of at least 15 eosinophils per high-power field on light microscopy.[9] The precise role of food allergy in EoE is not well defined; IgE-mediated and non–IgE-mediated mechanisms may be involved in the pathogenesis. The most common food allergens implicated in the pathogenesis include milk, egg, wheat, and soy. Numerous other foods have been implicated in the pathogenesis of EoE, and a common approach to treatment is initial elimination of milk, egg, wheat, soy, peanut, tree nuts, fish and shellfish. If dietary elimination is not successful or not feasible for the patient, then topical (swallowed aerosol) inhaled steroids (e.g. fluticasone or budesonide) may be swallowed rather than inhaled to treat the inflammation.

EGE is less common than EoE and, like EoE, it is believed that its pathogenesis involves both IgE-mediated and non-IgE-mediated mechanisms. Common symptoms of EGE include vomiting, abdominal pain, diarrhea, and failure to thrive/weight loss. Multiple food allergens are often implicated, although response to dietary elimination of the most common food allergens (milk, egg, wheat, soy, peanut, tree nuts, fish, and shellfish) is typically less successful than dietary elimination reported in patients with EoE. Topical (swallowed aerosol) inhaled steroids (e.g. fluticasone and budesonide) may provide some benefit; however, systemic steroids are often necessary for disease control.

FPIES is a non–IgE-mediated disease usually occurring in infants.[10] Characteristic symptoms of FPIES manifest as repetitive emesis with or without diarrhea accompanied by lethargy occurring 2–4 hours after ingestion of the offending food protein. The risk of abrupt volume loss, hypotension, and potential for bowel perforation makes this a medical emergency. Treatment is reliant on rehydration. Ondansetron may be helpful in managing acute FPIES reactions. Milk and soy are most commonly implicated, along with less common food allergens, such as rice, oats, fruits, or vegetables. FPIES is outgrown in the majority of affected children by 3 years of age but may be protracted for many years in a smaller subset of patients.

Celiac disease is an immune-based reaction to gluten, a storage protein for wheat, barley, and rye. The small intestine is typically affected in genetically predisposed individuals, and symptoms resolve with gluten avoidance. Symptoms of celiac disease are variable and may include diarrhea, steatorrhea, weight loss, bloating, flatulence, abdominal pain, and also non-GI symptoms, such as abnormal results on liver function tests, iron deficiency anemia, bone disease, and skin disorders. Celiac disease is detected with serological testing of celiac-specific antibodies and confirmed by duodenal mucosal biopsy, both of which should be performed while the patient is on a gluten-containing diet.[11]

PATHOPHYSIOLOGY

Food allergy results from a breakdown of oral tolerance (or failure to develop it); foods which are ordinarily harmless may then trigger an immune response that results in harmful adverse symptoms upon exposure. Maintaining tolerance requires a delicate balanced effort from multiple arms of the immune system. Deviation from the protective response may result in the development of an allergic response.

PROPERTIES OF FOOD ALLERGENS

An intact GI mucosal barrier is required to maintain tolerance. The first line of defense against the mucosal immune system is a hydrophobic layer of mucin oligosaccharides, which serve to trap antigen.[12] Secretory IgA is also a part of the outer layer of intestinal defense against dietary antigens. Dietary antigens must then penetrate the intestinal epithelium, which is maintained by epithelial junction complexes (adherens junctions) and tight junctions. Intestinal epithelial barrier dysfunction may play a role in food allergen sensitization. Alterations in the integrity of junctional complexes may be induced by calcineurin inhibitors, and this can result in food allergen sensitization. Genetic defects, such as those in individuals with filaggrin mutations, a protein that binds to keratin and is important for epithelial cell integrity, may predispose individuals to increased risk of EoE. Other factors that have been shown to affect intestinal permeability include viruses, alcohol, and nonsteroidal anti-inflammatory drugs (NSAIDs). These environmental exposures may alter intestinal epithelial integrity, thus allowing antigen to interact with the next layer of defense, mucosa associated lymphoid tissue (MALT; Chapter 20).

MALT is composed of lymphocytes, antigen-presenting cells (APCs), stromal cells, and other immune cells in the lamina propria. It is within MALT that dendritic cells (DCs) interact with dietary antigens.

There are several common characteristics among the most commonly allergenic foods: *(i)* relatively small molecular weight, generally less than 70 kilodaltons (kDa); (ii) an abundant source of the relevant allergen; *(iii)* glycosylation residues; *(iv)* water solubility; and *(v)* resistance to heat and digestion. These characteristics allow the proteins to stay intact until reaching the small intestine, where they initiate a T-helper cell-2 (Th2) response that results in production of specific IgE and eventual allergic disease. *Glycosylation* refers to the reaction by which carbohydrates are attached to molecules: in food allergens, the carbohydrate is most often attached to a protein. Carbohydrate residues surrounding proteins may be important in initiating the immune response. For example, interaction with DC-specific intercellular adhesion molecule–grabbing nonintegrin (DC-SIGN), a c-type lectin expressed on APCs that identifies conserved carbohydrate residues, has been shown to mediate recognition of the major peanut protein, Ara h 1. This interaction allows DC activation and Th2 skewing of naïve human T cells.

KEY CONCEPTS

Risk Factors for Fatal Food-Induced Allergic Reactions

Peanut and/or tree nut allergy
Delay in administration of autoinjectable epinephrine
Preexisting and/or poorly controlled asthma
Concomitant use of beta-blocker medications
Teen and young adult age groups

Once the Th2 response is initiated, it is strengthened through the induction of interleukin-4 (IL-4) signaling. IL-4 signals B cells to undergo class-switch recombination and begin producing IgE. Basophils have been implicated as a likely contributor of early IL-4 production and may play an important role in priming the T-cell response to allergens.

The Allergic Response

Allergenic food proteins that survive the initial stages of digestion are taken up by the APCs in MALT. Mucosal DCs may encounter antigen through *(i)* extending dendrites through the paracellular space between epithelial cells to sample luminal contents; *(ii)* directly interacting with the epithelial cells; and *(iii)* taking up antigen in the Peyer patch. Once contact with the antigen is established, the antigen is processed and loaded onto major histocompatibility complex (MHC) class II molecules on the cell surface, costimulatory molecules necessary for T-cell activation are upregulated, and chemotaxis to the draining lymph node occurs. Once a DC encounters a T-cell receptor with the same specificity as the peptide antigen, an immune response ensues. In the presence of cytokines, such as IL-4, IL-5, and IL-13, the responding T cell is programmed to be a Th2 cell. The Th2 cell will then signal B cells to generate IgE antibodies.

Soluble IgE that is produced by B cells circulates and binds to the surface of mast cells and basophils. Mast cells are found in skin, the gut, and the respiratory tract and are located adjacent to nerves and blood vessels. When an allergen is encountered and recognized by cell-bound IgE, calcium influx ensues, activating the mast cell. Once activated, the mast cell degranulates and releases vasoactive compounds and proteases, including histamine, platelet-activating factor, tryptase, chymase, carboxypeptidase, and heparin, resulting in the characteristic symptoms of an allergic reaction: urticaria, angioedema, flushing, nausea, vomiting, abdominal pain, diarrhea, wheezing, coughing/bronchospasm, rhinorrhea, and hypotension/syncope. Symptoms may occur alone or in combination and typically appear within minutes of ingestion.

Natural History

The majority of food allergies are outgrown. Allergies to peanut, tree nuts, fish, and shellfish are more likely to persist.[13] Clinical characteristics and laboratory measures may help predict which food allergies will be outgrown and which are more likely to be lifelong.

CLINICAL PEARLS

Important Diagnostic Considerations

The patient's history should support a diagnosis of immunoglobulin E (IgE) –mediated food allergy before performing either serum-specific IgE testing or the skin prick test.

95% predictive probability cutoffs have been established for only a few foods, including cow's milk, hen's egg, and peanut.

Even with negative specific IgE serum testing or skin testing, the patient could be allergic if he or she has a convincing history. In this case a physician-supervised oral food challenge may be required to confirm the presence or absence of an IgE-mediated food allergy.

Testing for food allergies should be limited to the food(s) in question, since positive IgE tests are not always clinically relevant. Unnecessary avoidance of foods may lead to nutritional deficiencies.

Cow's milk is typically one of the first foods introduced to infants in the form of infant formula: it is present in diets across cultural groups and is one of the most common allergens globally. Fortunately, cow's milk allergy is typically outgrown without intervention. Studies of natural resolution vary but about 50% of children with milk allergy develop tolerance between 5 and 10 years of age.[13] High levels of milk-specific IgE generally indicate a higher likelihood of persistent disease, but as many as 60% of children whose milk-specific IgE level peaks at over 50 kU/L will achieve natural tolerance by age 18 years. Up to 75% of children with reactions to uncooked milk can tolerate baked milk products. Consumption of heated milk products has been associated with accelerated acquisition of tolerance.[14]

Hen's egg allergy is another common food allergen across cultural groups. Most of the allergenic proteins in hen's egg are in the egg white. Allergy typically develops in the first year of life, while in some children, especially those with atopic dermatitis, it may develop before 4 months of age.[13] Similar to cow's milk allergy, egg allergy usually resolves during childhood without intervention. Roughly 50% of individuals with egg allergy in infancy develop natural tolerance between 6 and 9 years of age. Baked egg is tolerated by approximately 70% of children with egg allergy.[15] Individuals who can tolerate baked egg are likely to develop tolerance to lightly cooked egg sooner compared with individuals unable to tolerate baked egg.[16]

Although the majority of individuals allergic to peanut will remain reactive throughout life, approximately 20% of individuals with peanut allergy may develop natural tolerance. Favorable prognostic factors include low levels of peanut-specific IgE antibodies in the first 2 years of life and decreasing levels of IgE sensitization by 3 years. Those with peanut-specific IgE ≥3 kU/L and skin prick test (SPT) wheal diameter >6 mm before 2 years of age are more likely to have persistent peanut allergy.[17]

Allergy persistence, regardless of the food allergen, has been associated with the following factors: *(i)* earlier age at diagnosis; *(ii)* concomitant presence of other allergic diseases (*e.g.,* allergic rhinitis, asthma, and eczema); *(iii)* severity of those allergic diseases; *(iv)* symptom severity after ingestion; and *(v)* lower threshold dose required to elicit a reaction. The higher the food-specific IgE level, the more likely it is that the allergy will persist. Allergy persistence has also been associated with the rate of change of food-specific IgE levels or SPT wheal sizes. In clinical practice, food-specific IgE levels are typically checked yearly except in patients whose specific IgE levels remain high and unchanged over several years.

DIAGNOSIS

The diagnosis of food allergy begins with obtaining a detailed medical history.[6] Food-induced allergic reactions result in reproducible characteristic symptoms, as described above. Validated testing modalities are only available for IgE-mediated food allergies and celiac disease. If the clinical history does not support either diagnosis, then food allergy serum or skin testing should not be done, since there is a risk of finding sensitization to allergens which are not clinically relevant and multiple studies have shown the dangers of unnecessary dietary avoidance. When the clinical history does support a diagnosis of food allergy, this can be confirmed by SPTs and detection of specific IgE in serum.

SPTs to food allergens can be performed in the office setting and are both safe and effective, with results being available within minutes. A positive result of the SPT reflects the presence of specific IgE bound to the surface of cutaneous mast cells, but as with serum IgE testing, a positive test result does not always indicate clinical reactivity. A positive test result is generally interpreted as 3 mm larger than the negative SPT control, and the larger the SPT mean wheal diameter, the more likely it is indicative of a clinically relevant response. Negative SPT results have been associated with a high negative predictive value and may lead the physician either to offer an observed challenge or to counsel the patient on dietary reintroduction, depending on the clinical history and circumstances.

Serum-specific IgE testing is useful in providing an objective measure of food-specific IgE antibody, especially if the patient cannot stop antihistamine therapy or has extensive skin disease making it impossible to perform the SPT, and may be helpful in counseling patients on the natural history of their food allergy. Predictive values have been established for a limited number of foods. Higher specific IgE levels are more likely to be associated with clinical reactivity, but the predictive value of specific IgE levels varies across patient populations and is affected by such factors as the patient's age, ethnicity, and time since last ingestion of allergen. Specific IgE levels may also help physicians decide when an oral food challenge is or is not appropriate.

The component-resolved diagnostic (CRD) test uses allergenic proteins derived from recombinant DNA technology or purification from natural sources to identify the patient's specific IgE reactivity to individual allergenic proteins rather than to the whole allergen. Diagnostic accuracy can be enhanced in specific circumstances (*e.g.,* for peanut and hazelnut).[18] However, CRD is not routinely used for diagnosis and has not been shown to provide significant additional clinical information for most allergens. CRD for peanut provides additional diagnostic information that is helpful to the clinician, but standardized decision-making cutoffs have not yet been established.

The basophil activation test (BAT) uses flow cytometry to detect upregulation of cell-surface molecules, such as CD63 and CD203c, after stimulation with allergen.[19] BAT has been reported to be superior to the SPT, the CRD test, and the whole-allergen-specific IgE test for diagnosis of peanut allergy; however, testing has not been standardized. Further research is needed to standardize the BAT and validate results with various food allergens.

The oral food challenge (OFC) remains the gold standard for the diagnosis of food allergy.[20] OFCs can be conducted in an open manner; with a placebo control, where the patient is blinded to the product being given; or in a double-blinded manner, with both the physician and patient blinded to the food being given to the patient. An open OFC is most commonly performed in clinical practice, while the double-blind, placebo-controlled food challenge is considered the diagnostic standard typically reserved for research studies. During the OFC, a standard serving size of the allergen is divided into 4–7 servings and administered over 60–90 minutes, with each dose being given 15–20 minutes apart. The initial amount fed to the patient is typically a very small proportion of the total serving, and each successive dose administers a larger amount of protein. At the first sign of an objective reaction, the OFC is stopped and appropriate treatment administered. In cases where anxiety or subjective symptoms may affect the interpretability of the OFC, a single-blind or double-blind placebo-controlled food challenge may be preferred.

MANAGEMENT

The patient with a food allergy must maintain strict avoidance of the food allergen to prevent an allergic reaction. Avoidance requires constant vigilance. Accidental ingestion is common, with reports showing that as many as 50% of children with a peanut allergy may experience an adverse reaction in a 2-year period and up to 75% over 10 years.[6] Individuals with food allergies and their caregivers must read ingredient labels closely, prevent cross-contact, communicate with restaurant staff when eating outside of the home, and be prepared to treat a reaction, when necessary.

Food allergy labeling laws in the United States require that the presence of the most common allergens (milk, egg, peanut, tree nuts, wheat, soy, fish, and crustacean shellfish) must be declared in simple English on the ingredient labels of all packaged foods. Individuals allergic to foods other than the eight most common allergens may have more difficulty with interpretation of ingredient labels. Ingredient labels may report “spices” or “natural flavors,” which could include a multitude of foods or food products not covered by food allergy labeling laws. Statements such as “may contain [allergen]” and “manufactured on shared equipment with [allergen]” are voluntary and not regulated. Allergen content in such products is unknown, and it is typically recommended that individuals with allergies avoid products with “may contain” labeling.

Children with milk allergy or with two or more food allergies have been shown to be at particular risk of growth deficiency. Nutritional counseling with a registered dietitian is encouraged for these patients. A registered dietitian will help educate the patient and his or her family on avoidance of food allergens, in addition to providing guidance on nutrient supplementation to avoid potential dietary deficiencies.

TREATMENT OF A REACTION

An acute reaction must be recognized and treated expeditiously. Food-induced fatalities are most commonly reported from ingestion of peanut and tree nuts, but any food allergen can induce a severe reaction. Fatalities have been associated with delay in administration of autoinjectable epinephrine, preexisting and/or poorly controlled asthma, and concomitant use of beta-blocker medications; there is increased mortality in teen and young adult age groups. Intramuscular autoinjectable epinephrine must be readily available to patients with IgE-mediated food allergies and is the first-line treatment for a food-induced allergic reaction. Patients with food allergies are encouraged to have a written emergency action plan that lists the signs and symptoms of an allergic reaction and details treatment of those symptoms.

PREVENTION OF FOOD ALLERGY

Exposure to antigen early in life is likely very important for shaping the appropriate immune response to foods. Primary exposure through the oral route is believed to predispose to the development of a tolerogenic response, whereas primary exposure through skin may result in sensitization.[21] Support for the theory of prevention through primary oral exposure has been strongly supported through epidemiological studies showing that some cultural groups that introduce peanuts to their children in the first year of life have a lower incidence of peanut allergy.[22] This theory has been strengthened through recent evidence demonstrating that children identified as being at high risk of developing peanut allergy (severe atopic dermatitis and/or egg allergy) are substantially protected against the development of peanut allergy if they regularly ingest peanut, from between 4 and 11 months of age through 60 months of age, compared with matched controls who avoid peanut.[23]

Evidence in favor of a compromised skin barrier as the primary site of sensitization was shown in the Avon Longitudinal Study of Parents and Children birth cohort study, which reported that infants who had peanut allergy were more likely to have had severe AD in the first 6 months of life and also to have been treated with application of peanut oil to the skin.[24] In children with AD, the outermost layer of skin (stratum corneum) contributes to skin barrier function. Patients with AD have increased transepidermal water loss (TEWL). Increased TEWL not only allows water loss through skin but also facilitates allergen penetration and resultant sensitization. Further work is required to understand whether emollient use may reduce the risk of AD development and possibly reduce the risk of developing food allergy.

The role of the microbiome is an intense area of study with regard to food allergy development. Microbial products in the gut flora interact with innate immune receptors, such as Toll-like receptors (TLRs) and relay signals implicated in the activation of regulatory T cells (Tregs), which are important in the promotion of tolerance. Activation of a specific TLR using nonpathogenic bacteria (probiotics) could conceivably prevent allergic disease. Unfortunately, studies investigating the role of probiotics in preventing allergic disease have not shown promise, probably because of the difficulty in identifying which specific strains of gut bacteria are beneficial. Encouragingly, new techniques, such as deep-sequencing technologies, are allowing better characterization of the gut flora. As techniques improve and our understanding deepens, there is hope that new therapeutic targets will emerge for food allergy prevention.

EXPERIMENTAL INTERVENTIONAL THERAPIES

The standard of care for IgE-mediated food allergy is avoidance of the potentially triggering allergen, treatment of a reaction with autoinjectable epinephrine, and dietary supplementation of potentially deficient nutrients in the diet of the patient with a food allergy. Allergen-specific immunotherapies are currently under investigation utilizing the oral, sublingual, and epicutaneous routes for the application of the allergen. Although currently no therapies have been approved by the US Food and Drug Administration for the treatment of food allergy, several of those being investigated are promising.

Oral Immunotherapy

Oral immunotherapy (OIT) is accomplished by mixing the allergenic food into a vehicle food, initially giving doses below the level that would trigger reactions in an allergic individual and gradually increasing the amount of protein ingested over time. The buildup phase of therapy typically lasts several months; once a maintenance dose of allergen is achieved, the patient has to ingest the allergen for a certain period (typically ≥1 years, possibly indefinitely) to maintain a protected, desensitized state. Most studies have focused on achievement of desensitization, which refers to a temporary increase in the threshold of allergen required to elicit a reaction and is dependent on regular exposure to the allergen.

OIT will induce significant desensitization in most patients who are able to tolerate therapy. However, sustained protection against an allergic reaction independent of ongoing allergen exposure (sustained unresponsiveness [SU]) has not been adequately measured; only a minority of individuals achieved SU in the few studies measuring this outcome.[25] Most individuals undergoing OIT will experience adverse reactions. Oral pruritus and transient abdominal pain are the most common problems; reactions are typically mild and do not require any treatment. Severe reactions, such as anaphylaxis, may develop during therapy; predisposing factors include infection, exercise, and allergen coexposure. GI symptoms are the most common reason for participants withdrawing from OIT trials, and EoE has occasionally been documented. Further work is needed to determine which patients are most likely to develop SU, who will tolerate OIT with few dose-limiting adverse events, and the mechanisms underlying the development of desensitization and SU.

The initial immune response detected in desensitization includes an increase in food-specific IgG4, decreased basophil and mast cell responsiveness, and an initial increase in allergen-specific IgE. Allergen-specific IgE then decreases gradually over time. After 6–12 months of therapy there appears to be a shift away from Th2 cytokine production in response to allergen toward a Th1 profile. Treg upregulation occurs later in the course of OIT, with studies showing increased function of antigen-specific $CD4^+CD25^+$ $FOXP3^+$ Tregs. Epitope mapping typically changes over time indicating different antigen-specific responsiveness. Unfortunately, there are no biomarkers that consistently predict successful desensitization or sustained unresponsiveness.

Sublingual Immunotherapy

Sublingual immunotherapy (SLIT) utilizes a food protein dissolved in a liquid medium and delivered beneath the tongue. The oral mucosa contains tolerogenic APCs: SLIT is thought to rely on these cells to induce a desensitized state. SLIT dosing utilizes microgram to milligram quantities of protein, whereas OIT protocols utilize gram quantities of protein. Increasing the amount of allergen given is limited by the concentration of available extracts and the volume of liquid that can be held sublingually.

Few studies have compared SLIT with OIT; current evidence indicates that SLIT has fewer side effects compared with OIT, but SLIT does not appear to induce a similar level of desensitization or achieve SU as often as OIT. Ongoing compliance with SLIT has also been reported as challenging. Additional studies are needed to reveal whether adjuvant therapy with SLIT increases efficacy and to understand whether SLIT could be combined with OIT to improve its safety.

THERAPEUTIC PRINCIPLES

Avoidance

Read ingredient labels closely. The eight most common food allergens are required to be disclosed on ingredient labels of foods manufactured and sold in the United States.

Minimize cross-contact with food allergens during meal preparation.
- Use utensils, cutting boards, and pans that have been thoroughly washed with soap and water.
- If you are preparing several foods, make the allergy-safe food first.
- Wash hands with soap and water before touching anything else if you have handled a food allergen.
- Wash counters and table with soap and water after making meals.

When eating at a restaurant, inform the waiter and cooking staff about food allergens.

Avoid buffets.

Treatment

Advise patients at risk of anaphylaxis to carry two autoinjectable epinephrine devices at all times.

Recommend a medical identification bracelet.

Provide an anaphylaxis emergency plan, and review indications for administration of autoinjectable epinephrine.

Demonstrate the appropriate use of autoinjectable epinephrine with a trainer device at the physician's clinic visits.

Epicutaneous Immunotherapy

Epicutaneous immunotherapy (EPIT) delivers allergen to the skin through application of an allergen-containing patch. Langerhans cells in the skin are activated and effector cell responses are downregulated. Peer-reviewed published data are currently lacking, but preclinical studies have demonstrated potential for clinical efficacy. The only published trial utilizing EPIT has reported an increased threshold of reactivity after 3 months of therapy in children with milk allergy.[26] Anaphylaxis has not been reported with EPIT; the most common side effect appears to be an eczematous response at the site of patch application.

CONCLUSIONS

ON THE HORIZON

Allergen-specific desensitization therapies are currently investigational but may be available for clinical use in the near future.
- Oral immunotherapy (OIT) exposes the allergic patient to progressively larger doses of ingested allergen in an effort to induce a desensitized state. Gram quantities of allergen are typically administered.
- Epicutaneous immunotherapy (EPIT) applies microgram amounts of allergen directly to the allergic patient's skin, resulting in an effort to increase the threshold of reactivity. EPIT patch is typically kept on skin for up to 24 hours at a time, and a new patch is applied daily. Few published studies to date have reported its efficacy.
- Sublingual immunotherapy (SLIT) involves sublingual administration of milligram quantities of allergen solubilized in a liquid formulation. Systemic reactions are rare; however, studies to date have not consistently shown benefit in tested subjects.

Diagnosis of food allergy is reliant on an understanding of its pathogenesis and proper application of available diagnostic tools. Management of food allergy requires education about avoidance of the allergenic food(s), dietary supplementation of missing nutrients, and recognition and early treatment of any allergic reactions. Although food allergy has increased in prevalence over the past two decades, preventive strategies, including early introduction of allergenic solids, may help curb this as yet unexplained epidemic. As our knowledge of food allergy grows, we can expect significant changes in our approach to the treatment of those affected in the years to come.

MULTIPLE-CHOICE QUESTIONS

1. A 3-year-old boy is seen in his primary care physician's office after having a reaction at a recent birthday party. His mother states that she noticed lip swelling and coughing within minutes after eating off a plate containing a variety of foods. The meal consisted of a hamburger with mustard, lettuce, onion, and pickles; potato chips; fruit punch juice; and a piece of candy containing chocolate, pecans, and caramel. Which of these foods the child ate most likely contributed to his reaction?
A. Mustard
B. Red dye #5 in the fruit punch
C. Chocolate
D. Pecan
E. Onion

2. A 14-year-old boy with a diagnosis of atopic dermatitis and multiple food allergies is seen in his primary care physician's office for his yearly well-child physical. His mother reports that he has been avoiding eggs, peanuts, tree nuts, fish, and shellfish since he was 2 years old. He has a history of anaphylaxis to peanuts, and documented sensitivity to eggs that resulted in worsening of his atopic dermatitis as an infant. Which of the following allergens is most likely to be tolerated in this child who is now 14 years old?
A. Egg
B. Peanut
C. Cashew
D. Tilapia
E. Shrimp

3. An 11-year-old male has recently been diagnosed with eosinophilic esophagitis (EoE). Which of the following is an appropriate long-term treatment option for him?
A. Daily oral prednisone
B. Avoidance of milk, egg, wheat, soy, nuts, and seafood
C. Monthly injections of omalizumab
D. Daily montelukast
E. Oral desensitization to milk, egg, and wheat

4. A new mother brings her 5-month-old child with severe atopic dermatitis into your office for evaluation. Is there anything you could tell her to decrease the likelihood of the child developing a food allergy?
A. Introduce egg products after 2 years of age.
B. Introduce wheat products after 2 years of age.
C. Introduce sweet potatoes at 6 months of age.
D. Introduce peanut products at 5 months of age.
E. Introduce shrimp at 3 years of age.

Eosinophil-Associated Gastrointestinal Disorders

Alex Straumann

The human gastrointestinal (GI) tract is the largest host-environment interface of the body, where the epithelial surface is exposed to an overwhelming load of diverse microorganisms as well as to dietary products. Commensal microorganisms, the so-called "intestinal microbiota," are currently regarded as an integrated part of the body involved in the regulation of several physiological functions (Chapter 14). In contrast, potentially pathogenic microorganisms of the luminal content must be recognized and, if possible, eliminated by the mucosal immune system. Several mechanisms are involved in maintaining a physical and functional barrier to stabilize body homeostasis. Besides the physical barriers, the mucosal immune system is of particular importance, with the evolutionarily ancient "innate" and the more specific and more diverse "adaptive" immunity (Chapter 20). Its task is to initiate an inflammatory response against invading microorganisms while maintaining a state of nonresponsiveness or tolerance to innocuous substances such as commensal bacteria or food antigens.

Each system of immunity relies on different cell types and gene products with characteristic modes of action. Eosinophils—part of the innate immune system—are present in the peripheral blood of healthy individuals and account for approximately 1–3% of peripheral leukocytes with an upper limit of the normal range of 350 cells per cubic millimeter of blood.[1] Tissue-dwelling eosinophils reside in the hematopoietic and lymphatic organs, such as the bone marrow, spleen, lymph nodes, and thymus. However, based on a comprehensive analysis of normal human tissues from almost all body organs, we know that the GI tract is the only nonhematopoietic organ showing significant numbers of tissue-dwelling eosinophils *under healthy conditions*.[2] The distribution of eosinophils is not homogeneous throughout the digestive tract, with the highest density of cells in the cecal and appendiceal region.[2] Under physiological conditions, the esophagus is the only segment of the digestive tract that lacks tissue-dwelling eosinophils.[2,3] Besides the resident eosinophils, a marked accumulation of eosinophils in the digestive tract can be seen under inflammatory conditions. Because eosinophils are nonspecific late-phase inflammatory cells, infiltration can occur in the context of any type of inflammation—*e.g.*, bacterial and parasitic infections, celiac disease, Crohn disease, and ulcerative colitis—independently of its cause.[1]

This chapter focuses on three idiopathic eosinophil-associated GI disorders, in particular idiopathic eosinophilic esophagitis (EoE), idiopathic eosinophilic gastroenteritis (EGE), and idiopathic hypereosinophilic syndromes (HESs) with GI manifestation (Table 46.1). The term "eosinophil-associated" denotes that the histological inflammatory response is characterized by an eosinophil-predominant tissue infiltration. Moreover, it is likely that eosinophils play a crucial role in the pathogenesis of these disorders. However, each of these conditions has different properties and probably has its own pathogenesis; to subsume them into one single category is quite arbitrary and based exclusively on descriptive features. EoE is definitely an esophageal-restricted disease with a benign long-term prognosis.[4] In patients with EGE, the inflammatory process can involve several segments of the GI tract; nevertheless, in clinical terms this chronic inflammation is also a benign disorder.[5] In contrast, HES is a multisystem disorder that may involve several organ systems, including the digestive tract, sometimes with a fatal outcome.[6] Despite these differences, all three conditions share the common features of being idiopathic, chronic, and eosinophilic, and although our understanding of the underlying mechanisms remains fragmentary, we may take the liberty of classifying them into one single category.

EoE is by far the most common eosinophil gastrointestinal disorder (EGID). Because of its clinical relevance, EoE is discussed in greater depth here than the other two eosinophil-associated disorders.

EOSINOPHILIC ESOPHAGITIS

Definition

In the latest consensus recommendations, the following conceptual definition was published: EoE represents a chronic, immune/antigen-mediated esophageal disease, characterized clinically by symptoms related to esophageal dysfunction and histologically by an eosinophil-predominant inflammation.[4] This definition shows that the diagnosis of EoE is based on clinical and on histopathological findings.

Epidemiology

Epidemiological information is essential to determine the clinical and socioeconomic impact of a disease. Therefore knowledge of the epidemiological parameters of a disease is crucial for identifying risk factors as well as pathogenetic mechanisms, for planning preventive measures, and for determining optimal treatment approaches.

Demographic Cornerstones

Cases of EoE have been reported worldwide and identified in those with a variety of ethnic backgrounds, including Caucasians, African Americans, Hispanics, and Asians. However, as there are no controlled data about geographical variations of prevalence, it remains unclear whether EoE is associated with any particular

TABLE 46.1 Eosinophil-Associated Gastrointestinal Disorders

Eosinophilic esophagitis (EoE)
Eosinophilic gastroenteritis (EGE)
Hypereosinophilic syndromes (HESs)

CLINICAL PEARLS

Eosinophil-Associated Gastrointestinal Disorders (EGID)

- All more common in males

Eosinophilic Esophagitis (EoE)

- Persistent solid food dysphagia/impaction, often with coexisting allergic diseases
- Structural changes may be present at endoscopy
- Diagnosis confirmed by histology
- Treatment includes:
  - Corticosteroids (swallowed or systemic)
  - Allergen-specific diets
  - Dilatation treatment for strictures

Eosinophilic Gastroenteritis (EGE)

- Nonspecific gastrointestinal symptoms due to eosinophilic infiltration of segments of GI tract; can affect all layers of the intestinal wall
- Diagnosis based on histology and exclusion of other causes of intestinal eosinophilia
- Treatment of serosal EGE is with systemic steroids; optimal treatment for other forms not yet defined

Hypereosinophilic Syndromes (HESs)

- Persistent peripheral blood eosinophilia >6 months
- Eosinophilic infiltration of several organ systems with related symptoms
- Gut and cardiac involvement associated with a poor prognosis
- Treatment strategies for patients with HESs include:
  - Corticosteroids
  - Cytotoxic agents
  - Interferon-α
  - Imatinib mesylate (for *PDGFRA*-associated HESs)

ethnic or racial groups, especially as most of the published studies have analyzed data from primarily Caucasian patients. EoE can be found in all age groups, but most studies report an average age between 34 and 42 years with a male-to-female risk ratio of 3:1.[7,8] EoE therefore affects mainly middle-aged male individuals with an atopic background.

Interestingly, age at diagnosis does not correlate with onset of EoE-attributed symptoms, which can be considered as the onset of disease. Several studies report a substantial time lag between onset of symptoms and time of diagnosis (diagnostic delay), which in some cases can be attributed to unawareness of sentinel features at endoscopy (doctors' delay). Often patients develop specific eating strategies, with careful chewing and avoidance of dry and rough food; despite a substantial impairment of quality of life, they bypass medical care (patient delay). An average diagnostic delay of 5 to 6 years has been reported from both North America and Europe.[7-9]

Incidence and Prevalence of Eosinophilic Esophagitis

Although considered a rare disease, several epidemiological studies from geographically confined regions indicate an increasing incidence and prevalence of EoE in the adult population during recent years.[7-9]

Probably the most conclusive epidemiological data originate from the geographically confined district of Olten, Switzerland, where a prospective population-based assessment strategy has been used with consistent diagnostic and enrollment procedures for evaluation of EoE. Between 1989 and 2009, EoE was diagnosed in 46 patients (76% males; mean age 41 ± 16 years). An average annual incidence rate of 2.45/100,000 was calculated. In the face of a constant diagnostic delay and the lack of EoE awareness programs, significantly more EoE cases were diagnosed from 2000–2009 compared with 1989–1999. Because EoE is clinically a benign disease affecting mainly younger individuals, the cumulative EoE prevalence rose to 42.8/100,000 in 2009. Extrapolating from this study, in North America and in Europe there is one patient with diagnosed EoE among every 2–3000 inhabitants. Current prevalence and incidence data of EoE are comparable with those of other chronic inflammatory diseases of the GI tract, for instance Crohn disease.

KEY CONCEPTS

Differential Diagnosis of Eosinophilic Esophagitis

- Gastroesophageal reflux disease (GERD)
- Infectious esophagitis (Herpes, *Candida*)
- Parasitic infection
- Drug-induced esophagitis
- Autoimmune disease (vascular and connective tissue diseases)
- Eosinophilic gastroenteritis with involvement of the esophagus
- Hypereosinophilic syndrome with involvement of the esophagus
- Crohn disease with involvement of the esophagus

Pathophysiology

Eosinophils' Natural Lifecycle

Eosinophils reside predominantly in three anatomical compartments: the bone marrow, blood vessels, and organs with mucosal surfaces. Eosinophils originate in the bone marrow from pluripotent stem cells. Their differentiation process is orchestrated mainly under the influence of three cytokines: interleukin (IL)-3, IL-5, and granulocyte macrophage–colony-stimulating factor (GM-CSF), leading to a fully granulated state before they migrate to the vascular space.[1] In particular, IL-5 is very specific for the eosinophil lineage; it stimulates the release of eosinophils from the bone marrow and extends their survival once they are in target tissue. Mice lacking IL-5 show a significant reduction in tissue eosinophilia, whereas mice overexpressing IL-5 show markedly increased peripheral eosinophilia.[10] A multistep process mediated by adhesion molecules on endothelial cells and corresponding ligands on eosinophils (P-selectin and β-1 and β-2 integrins) enables migration from the vascular space into tissues. This is orchestrated by T-helper cell-2 (Th2) cytokines (IL-4 and IL-13) that induce expression of cell surface ligands of the β-integrin family, such as very late antigen (VLA)-4 (β-1 integrin) on the surface of eosinophils and their counterligands on endothelial cells including vascular cell adhesion molecule (VCAM)-1.[9] Various chemoattractants—released within local mucosal environments—provoke eosinophil migration, including leukotriene B_4, platelet activating factor, chemokines, and bacterial products.[9,11] Eotaxin is important, as it binds the chemokine receptor CCR-3 on eosinophils. Eosinophils are absent from the gastrointestinal tract in mice lacking eotaxin-1.[12]

The Role of IgE in Eosinophilic Esophagitis

In up to 70% of EoE patients, there is a history of concomitant atopic diseases such as allergic rhinitis, bronchial asthma, and atopic dermatitis; elevated total serum immunoglobulin E (IgE) levels are found in about 70% of EoE patients.[7-9] Therefore both food and airborne allergens have been implicated as factors in inducing and maintaining the eosinophilic inflammation.[13] Children with esophageal eosinophilia not responding to pharmacological and/or surgical antireflux therapy showed marked improvements after being given elemental formulas.[7-9] This observation suggests that EoE could represent an IgE-mediated allergic disease in which food proteins play an important role.

On the other hand, clinical trials of targeted food elimination diets, or treatment with IgE-blocking agents, have failed to show an IgE-mediated mechanism.[7-9] Moreover, the identification of causative foods based on empiric elimination diets correlated poorly with the findings of IgE-sensitization patterns to food allergens as determined by skin prick tests (SPTs) and/or blood tests for food-specific IgE.

In summary, the current understanding is that IgE plays at most a subsidiary role in the pathogenesis of EoE and that neither IgE-based diagnostic tools nor IgE-targeted treatment is helpful.[13]

Th2-Mediated Immune Response

EoE is characterized by infiltration with cells having a characteristic Th2-type inflammatory pattern (Fig. 46.1) (Chapter 16).[14] In esophageal biopsy specimens of EoE patients, increased numbers of lymphocytes (T cells and B cells) and mast cells are found as well as increased expression of the cytokines IL-5 and IL-13.[14] The crucial role of IL-5 and IL-13 in the pathogenesis of EoE has been demonstrated in various experimental models.[15] As a proof-of-concept study of aeroallergen-induced esophageal eosinophilia, intranasal allergen challenge with *Aspergillus fumigatus* resulted in an infiltration of eosinophils in both the esophagus and the bronchi, whereas tissue eosinophilia did not develop in IL-5–deficient mice. Direct delivery of IL-13—the other important cytokine of the Th2 immune response—into the pulmonary tree induced esophageal eosinophilia, which can be blocked by antihuman IL-13 antibody.[15] Interestingly, esophageal epithelial cells produce the important eosinophil chemoattractant eotaxin-3 after IL-13 stimulation, through a transcriptional mechanism dependent on *STAT6*.[10] Esophageal eotaxin-3 strongly correlates with tissue eosinophilia, and eotaxin-3 is one of the most induced genes in patients with EoE.[12] Moreover, a single nucleotide polymorphism in the eotaxin-3 gene (*SNP* 2496 T→G) is linked to increased disease susceptibility for EoE.[12]

Accumulation and activation of eosinophils in the esophagus is followed by release of various granule proteins and cytokines. These mediators can exert cytotoxic effects (*e.g.,* major basic protein [MBP], eosinophil-derived neurotoxin [EDN], eosinophil peroxidase [EPO]), or they can contribute to perpetuation of the inflammatory response through activation of a wide range of other inflammatory cytokines, such as IL-1, IL-3, IL-4, IL-5, IL-13, IL-15, GM-CSF, TNF-α, RANTES, MIP1-α, and transforming growth factor (TGF)-β, highlighting the complexity of the pathophysiological mechanisms.[8,9]

Esophageal Remodeling

Unbridled eosinophilic inflammation leads to fibrosis and angiogenesis with an ensuing loss of elasticity of the esophageal wall and luminal narrowing. This phenomenon is called tissue remodeling and has been described in clinical studies as well as in animal models.[8,16,17] Although the exact mechanism is not known, eosinophils and subepithelial mast cells expressing tryptase are critically involved in this process via secretion of TGF-β1. TGF-β1 appears to be involved in numerous processes relevant to allergic inflammation, including regulation of profibrotic processes and modulation of smooth muscle contraction with increased contractility, thereby potentially contributing to clinical symptoms such as dysphagia and bolus obstruction in EoE patients. Furthermore, there is growing evidence in murine models that IL-5 and IL-13, the two crucial cytokines involved in tissue eosinophilia, also induce esophageal remodeling.[17]

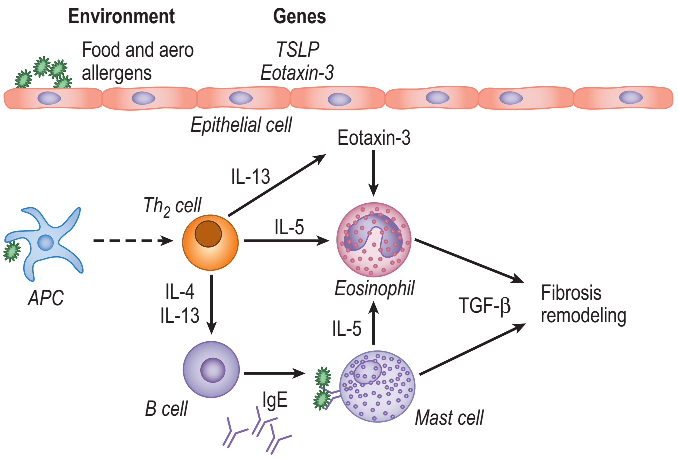

FIG 46.1 **Immunopathogenesis of Eosinophilic Esophagitis.** The current understanding of cellular and molecular mechanisms in the pathogenesis of eosinophilic esophagitis (EoE) involves a complex interaction of genetic and environmental factors. EoE disease susceptibility is linked to single nucleotide polymorphisms (SNPs) in the eotaxin-3 and thymic stromal lymphopoietin (*TSLP*) gene. A sensitization to food and aeroallergens has been noted. Two possible pathways can lead to accumulation of eosinophils in the esophageal wall. First, allergens can be recognized by antigen-presenting cells (APCs), such as dendritic cells, and can activate a type 2 helper T-lymphocyte (Th2) immune response to induce the release of eosinophil-specific cytokines such as interleukin (IL)-5 and IL-13 and subsequently the production of eotaxin-3, which is a potent chemoattractant for eosinophils. Second, allergen exposure can result in the cross-linking of immunoglobulin E (IgE) receptors on mast cells, leading to release of specific inflammatory mediators, which boost directly or through stimulation of epithelial cells' accumulation of eosinophils in the esophageal layers. Both eosinophils and mast cells produce transforming growth factor (TGF)-β, a potent cytokine involved in fibrosis and smooth muscle contraction that promotes tissue remodeling, leading to loss of elasticity of the esophageal wall and luminal narrowing.

Application of the topical corticosteroid budesonide markedly decreased expression of fibrosis-related markers such as TGF-β1 and tenascin C in esophageal tissue, suggesting that antiinflammatory treatment might interrupt or even reverse remodeling of the esophagus.[7]

Clinical Manifestation of Eosinophilic Esophagitis

The predominant symptom of adult EoE is dysphagia for solids, often leading to long-lasting food impaction requiring endoscopic bolus removal. Because EoE patients rapidly develop specific

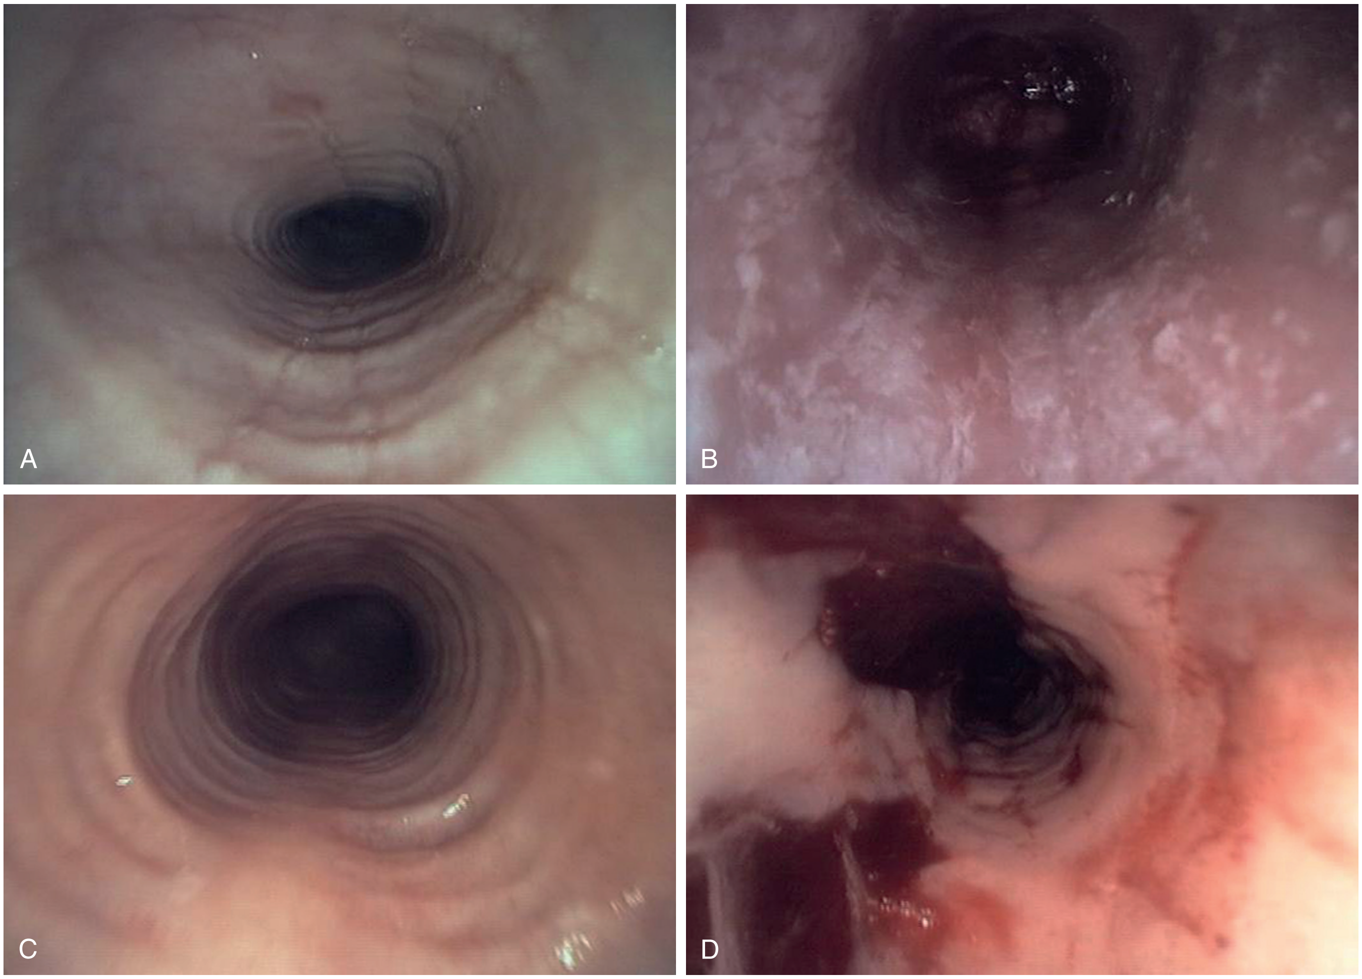

FIG 46.2 **Endoscopic Findings in Eosinophilic Esophagitis (EoE).** Representative endoscopic pictures of active eosinophilic esophagitis showing loss of vascularity and red furrows (A), whitish exudates (B), corrugated rings (C), and a long-distance stricture with a deep laceration after dilatation (D).

eating strategies, a careful evaluation of changes in eating habits is required.[18] EoE patients tend to chew carefully and avoid dry or rough food. Dysphagia and food impaction are reported increasingly with age. A minority of patients report symptoms akin to gastroesophageal reflux disease (GERD) swallowing-unrelated chest pain, and upper abdominal pain. In contrast, food refusal and failure to thrive may be observed in children, as dysphagia is less easily expressed in this age group. Children often report GERD-like symptoms such as heartburn and reflux, vomiting, and abdominal pain; less frequently, they report diarrhea (Table 46.2).[7]

TABLE 46.2 **Symptoms of Eosinophilic Esophagitis**

Adults	Children
Dysphagia	Food aversion/food refusal
Bolus obstruction	Vomiting/regurgitation
Nonswallowing-related chest pain	Abdominal pain
	Failure to thrive
	Dysphagia
	Heartburn/reflux
	Bolus obstruction
	Diarrhea

Endoscopy and Histology

Endoscopy shows a heterogeneous mix of abnormalities: subtle reddish, longitudinal furrows and white exudates may occur, reflecting local edema and acute inflammation, respectively. Transient or fixed corrugated rings as well as crêpe paper mucosa may be observed due to loss of mucosal elasticity and, most likely, chronic eosinophilic inflammation (Fig. 46.2A–D). The five major endoscopic signs of EoE are summarized in an EoE Endoscopic Reference Score (EREFS), a validated scoring instrument that should be used for the structured assessment of endoscopic activity.[19] Of note, because endoscopic features may be minimal in EoE, histological examination is recommended in every patient presenting with dysphagia.[7,8] The diagnosis of EoE is based on typical esophageal symptoms and characteristic histological findings (≥15 eosinophils/high power field [×400]), after exclusion of other esophageal diseases associated with an eosinophilic infiltrate of the mucosa (*e.g.*, GERD).[4] Several biopsies should be taken in EoE: tissue eosinophils can be patchily distributed in EoE, whereas eosinophils appear superficially along the luminal surface.[4] Because white exudates correspond to eosinophil aggregations and microabscesses (Fig. 46.3), biopsies should preferably be taken from these areas.

Treatment

As a result of recent advances in the understanding of the natural course of the disease, at least three reasons have been determined to treat EoE: (a) improvement of quality of life after resolution of the swallowing disturbances; (b) reduction of the risk of severe esophageal injury by preventing long-lasting food impactions; and (c) prevention of esophageal remodeling.[8] The current treatment options can be summarized as the three D's (Drugs, Diet, and Dilatation) and are presented in Table 46.3.

TABLE 46.3 Current Treatment Options for Eosinophilic Esophagitis: The Three D's (Drugs, Diet, and Dilatation)

THERAPEUTIC OPTIONS
Drugs
• Swallowed topical corticosteroids (budesonide, fluticasone)
• Systemic corticosteroids (prednisone)
• Biologicals (monoclonal antibodies against interleukin [IL]-13, IL-5)
• Immunosuppressants (azathioprine, 6-mercaptopurine)
• Antiallergic agents (CRTH2 blockers)
Diets
• Targeted elimination diets (individualized based on results of allergic testing)
• Empiric "6-Food" elimination diet (milk, soy, wheat, nuts, eggs, seafood)
• Elemental diet (protein-free formulas)
Dilatation
• For strictures

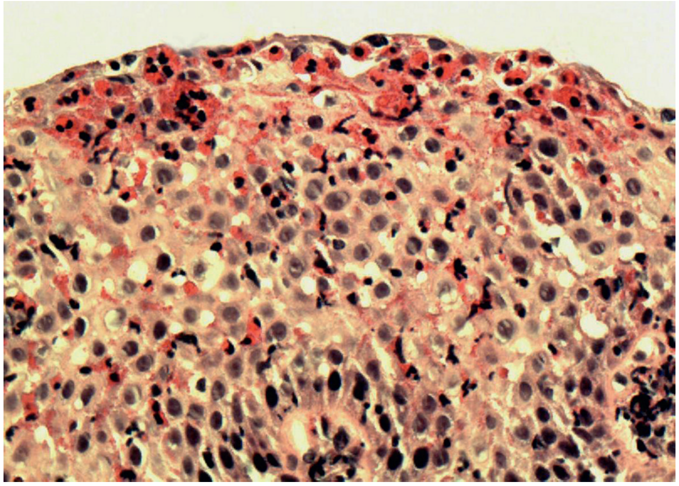

FIG 46.3 **Histopathological Findings in Eosinophilic Esophagitis (EoE).** Representative histological pictures of active eosinophilic esophagitis showing a dense infiltration of the squamous epithelium with eosinophils forming microabscesses.

Drugs

Acid suppression with proton pump inhibitors (PPI) is not usually effective in relieving symptoms and resolving eosinophilic inflammation in patients with EoE. However, patients with concomitant GERD, and a subgroup of EoE patients with "PPI-responsive" EoE, may respond to treatment with PPI. Therefore PPI therapy should not be considered as first-line treatment but instead used as cotherapy in patients with secondary or coexisting GERD.[4,8]

Systemic and topical corticosteroids show comparable effectiveness in resolving signs and symptoms of active EoE in both children and adults.[8] As topical steroids have fewer side effects, they are recommended as first-line therapy. Short-term use of systemic corticosteroids may be limited to emergent cases, such as dysphagia requiring hospitalization, patients with dehydration due to swallowing difficulties, or patients with symptoms refractory to topical steroids. Discontinuation of topical and systemic corticosteroids is usually followed by recurrence of the disease within a few weeks.[8]

Antiallergic drugs have been found largely ineffective in EoE treatment. Cromolyn sodium has no apparent therapeutic effect, and although leukotriene receptor antagonists have been shown to induce symptomatic relief, they do not affect esophageal eosinophilia.

Only limited data are available for targeted therapy with novel biological agents or immunosuppressants. The most impressive effect on symptoms, inflammation, and molecular abnormalities has been demonstrated with QAX576, a monoclonal anti-IL-13 antibody. Mepolizumab (anti-IL-5) significantly reduced esophageal eosinophils in adult EoE patients with only minimal effects on clinical improvement.[7,8] Treatment of EoE patients with the anti-TNF-α antibody infliximab did not reduce eosinophilic tissue infiltration or improve symptoms, even though massive expression of TNF-α has been shown in the squamous epithelium of the esophagus in active EoE. The immunosuppressants azathioprine and 6-mercaptopurine were effective in inducing and maintaining remission in three corticosteroid-refractory EoE patients. However, further evaluation of these alternatives for corticosteroid-refractory EoE is needed before they can be implemented into daily clinical practice.

Diet

Several prospective uncontrolled trials have been conducted to assess the potential of three different diets in treating EoE. Individually tailored so-called targeted elimination diets, empirical six-food elimination diets (removal of the six most common allergenic foods such as dairy, eggs, wheat, soy, peanuts, fish/shellfish), and a protein-free elemental diet have all shown efficacy in active EoE.[7-9] The choice of a specific dietary therapy requires that the patient's lifestyle and family resources be considered. So far, dietary treatment has been more effective in children than in adults. Overall, the value and the feasibility of dietary therapy require further evaluation.

Dilatation

Esophageal dilatation leads to long-lasting symptom relief but does not influence the underlying inflammation. It should therefore be reserved for patients who present with functional esophageal narrowing (strictures, stenosis) that is refractory to drug therapy. Endoscopic dilatation should be performed with caution, as it carries a risk of esophageal injury, although recently published large series suggest this risk is not as great as originally thought.[7,8]

IDIOPATHIC EOSINOPHILIC GASTROENTERITIS

Definition and Classification

EGE is a rare, heterogeneous, and poorly defined condition. It is characterized by chronic-recurrent tissue infiltration of the GI tract with eosinophils.[5] The diagnosis is based on the following three criteria: *1) nonspecific GI symptoms; 2) eosinophilic infiltration of one or more areas of the GI tract; and 3) exclusion of other causes for the intestinal eosinophilia.*[5] No consensus has yet been reached regarding the histological criteria for diagnosing EGE. This may be related to the fact that healthy gastric and intestinal mucosa harbors eosinophils under physiological conditions and so it is difficult to establish "normal" cell numbers.

EGE can be subclassified either according to the segments of the GI tract affected by the process or according to the depth of the eosinophilic infiltration.[5] The latter (or Klein) classification system distinguishes between mucosal, muscular, and serosal forms of EGE.[5] Parasitic infections, inflammatory bowel disease, connective tissue diseases, side effects of drugs, and lymphoproliferative malignancies must be ruled out before a diagnosis of EGE can be established.[5]

Epidemiology and Natural History

EGE predominantly affects male children and adults. In contrast to EoE, EGE is a very rare disease. During the 70 years since it was first described by Kaijser in 1937,[19a] approximately 200 cases have been reported in the literature. Although EGE is likely a chronic disorder, its natural course is still poorly defined.

Clinical Presentation

The clinical manifestation of EGE depends on its location within the GI tract and on its depth of infiltration of the intestinal wall. Mucosal involvement is typically associated with vomiting, diarrhea, abdominal pain, weight loss, failure to thrive, and either occult or frank bleeding. Involvement of the muscular layers may lead to signs and symptoms of intestinal obstruction, whereas patients with serosal involvement typically complain of bloating and can present with ascites. Peripheral blood eosinophilia is observed in approximately two-thirds of EGE patients.[5]

Diagnostic Measures

The mucosal form of the disease can be visualized by endoscopy. The findings are usually not spectacular and include thickening of the intestinal folds with deformation of the luminal configuration, diminished peristalsis, and an erythematous and friable mucosa. Moreover, endoscopy enables representative biopsy samples to be taken for histological confirmation of the diagnosis.[5] Patients with suspected serosal disease should be evaluated by laparoscopy; findings for this form of EGE include ascites, whitish nodules, and thickening of the parietal and visceral peritoneum.[5]

The muscular form of EGE can be detected by CT scan or conventional radiological examinations. Diagnostic confirmation is hampered by the difficulty in obtaining histological samples. Most reported cases of muscular EGE have been diagnosed after surgical resection of an intestinal obstruction or suspected malignancy.

Treatment

EGE is an uncommon disease, and therefore no therapeutic trials have been done. Case reports and small case series have reported responses to a variety of agents, including corticosteroids, PPIs, mast cell stabilizers, antihistamines, and leukotriene antagonists as well as surgical resection of strictured segments.[5,20]

Patients with the serosal type typically respond to steroid therapy; however, optimal treatment is not yet defined for other forms of EGE. Based on these limited data, initial treatment should be with PPIs, with a switch to systemic corticosteroids in the case of nonresponse. Unfortunately, the relapsing nature of the disease means long-term treatment may be needed with oral corticosteroids, with the inevitable risk of side effects. Leukotriene inhibitors should be evaluated in patients with frequent flare-ups.

HYPEREOSINOPHILIC SYNDROMES WITH GASTROINTESTINAL INVOLVEMENT

Definition and Classification

The HESs are a heterogeneous group of rare disorders characterized by 1) persistent peripheral blood eosinophilia with more than 1500 cells/mm^3 for a period of >6 months; 2) no known cause of eosinophilia; and 3) signs and symptoms of organ involvement.[6,21] Recent efforts have led to reclassification of these disorders according to the recognition of several clinical subtypes and new biomarkers. Currently recognized subtypes include fip1-like1/platelet-derived growth factor receptor α (*FIP1L1-PDGFRA*)-associated HESs, lymphocytic variant HESs, chronic eosinophilic leukemia, and familial eosinophilia.[22,23] Independent of this subclassification, the eosinophilic infiltration can affect the cardiovascular system (90%), the peripheral and central nervous systems (90%) including the retina, the coagulation system (80%), the skin (55%), the respiratory system (50%), the liver and spleen (35%), and the GI tract (25%).

Epidemiology and Natural History

HESs, similar to the other idiopathic eosinophilic disorders, predominantly affect middle-aged males, with a male-to-female ratio of 3 : 1. Onset of the disease is commonly between 20 and 50 years of age. Data about its prevalence or incidence are not available.[6,21]

Clinical Presentation

HES has a gradual onset, presenting initially with general symptoms such as anorexia, fatigue, weight loss, fever, abdominal pain, and night sweats. Throughout the course of the disease, the clinical manifestations vary according to which organs are involved. With GI involvement, abdominal pain and diarrhea with malabsorption have been reported, but the leading sign is hepatosplenomegaly, either due to eosinophilic infiltration or secondary to congestive heart failure. During its long-term course, extraintestinal manifestations or lymphoproliferative conditions may occur and facilitate the definite diagnosis. The ultimate prognosis depends on the extent of end organ damage. Intestinal manifestations and cardiac involvement are associated with poor prognosis and risk of fatal outcome, whereas patients with skin disease generally have a milder course.[6,21]

Immunopathogenesis

HESs encompass several disease processes with different pathogenic mechanisms. One form is characterized by a significant elevation of the eosinophilopoietic cytokine IL-5 in serum. Recently an IL-5–independent form of HES has been described in which a tyrosine kinase is overexpressed due to gene fusion.[22,24] Notwithstanding the heterogeneity of underlying mechanisms, the clinical manifestation of HES is similar, with eosinophil-mediated end organ tissue damage.

Treatment

Like EGE, HES is a rare disorder, and no prospective treatment studies have been carried out to date. Treatment strategies for patients with HESs aim to lower the eosinophil tissue infiltration. Corticosteroids have been used for decades to treat HESs and remain first-line therapy, except for *PDGFRA*-associated HESs. Cytotoxic agents, such as hydroxyurea, vincristine, and chlorambucil, have been successfully used in corticosteroid-refractory patients. Interferon-α is reported to be useful in patients with mucosal ulcerations.[23] The tyrosine kinase inhibitor imatinib mesylate has been shown to induce prolonged remissions in patients with *PDGFRA*-associated HESs. Future studies will show whether monoclonal antibodies against IL-5 could prove to be a valuable approach, given that patients with HESs often have high levels of IL-5.[25]

SUMMARY

ON THE HORIZON

- Clinical research is needed to:
  - Improve diagnostic criteria
  - Implement new diagnostic tools
  - Achieve early diagnosis
- Goals of clinical research are early treatment to improve quality of life and avoid tissue remodeling in patients with eosinophilic esophagitis (EoE).
- Multicenter clinical studies are needed to evaluate alternative treatment strategies (biologicals, immunosuppressants) for steroid-refractory EoE.
- Translational medicine will help to identify cellular and molecular factors involved in fibrosis of the esophageal wall to understand the molecular mechanisms of tissue remodeling.

Much ground still remains to be covered in diagnosing and treating patients suffering from the three eosinophil-associated GI disorders:

EoE is a common disease but challenging to diagnose due to its confusing endoscopic features. Patients, usually males, present with recurrent dysphagia and food impaction as well as coexisting allergic airway diseases. Untreated EoE can induce structural changes of the esophagus, eventually leading to an extremely fragile and rigid esophageal wall structure with increased risk for complications, including perforation. Effective treatments for adult patients with EoE include swallowed topical (or, seldom, systemic) corticosteroids, hypoallergenic diets, and esophageal dilatation. Though quality of life is substantially diminished in this chronic disorder, life expectancy is not affected.

EGE, a rather rare disorder affecting predominantly males, may involve the entire GI tract, or it may be restricted to isolated segments and affect mucosal, muscular, and serosal layers of the intestinal wall. Clinical manifestations depend on location and depth of the infiltration. Mucosal involvement, the most frequent subtype, is typically associated with vomiting, diarrhea, abdominal pain, and weight loss. The muscular form may mimic intestinal obstruction or acute abdomen. Patients with the serosal form complain mainly of bloating and ascites and usually respond dramatically to corticosteroids.

HESs are a heterogeneous group of rare disorders, characterized by persistent peripheral blood eosinophilia with more than 1500 cells/mm^3 for longer than 6 months, no known cause of eosinophilia, and signs and symptoms of organ involvement. Prognosis depends on the degree and location of the eosinophil-mediated end-organ tissue damage.

MULTIPLE-CHOICE QUESTIONS

1. Eosinophilic esophagitis:
   - **A.** Is the most common entity among the eosinophil gastrointestinal disorders (EGIDs)
   - **B.** During the natural course of the disease, often involves stomach and small bowel
   - **C.** Is mainly triggered and driven by food-antigens
   - **D.** Immunoglobulin E (IgE)-based testing plays a crucial role in the identification of causative foods
2. Eosinophilic esophagitis:
   - **A.** Must be treated only when a patient's quality of life is markedly impaired
   - **B.** Can be treated with drugs, diet, or dilatation
   - **C.** Dilatation is regarded as first-line treatment due to the rapid symptom resolution
   - **D.** Swallowed topical steroids and elimination diet have a comparable efficiency
3. Eosinophilic gastroenteritis:
   - **A.** Is a rare disease with unclear pathogenesis
   - **B.** Can be diagnosed only after exclusion of infections and intestinal allergies
   - **C.** Can involve each segment of the gastrointestinal tract
   - **D.** Swallowed topical steroids are currently considered as first-line drugs
4. Hypereosinophilic syndromes:
   - **A.** Have an unforeseeable and sometimes even fatal natural course
   - **B.** Involve mainly the gastrointestinal tract and seldom other organ systems
   - **C.** Encompass a group of entities with different immune pathogeneses
   - **D.** Require a comprehensive hematological and multisystem examination

47

Allergic Disorders of the Eye

Virginia L. Calder, Amirah Mohd-Zaki, Valerie Saw

Allergic disorders of the eye range from the mild conditions of seasonal and perennial allergic conjunctivitis (SAC, PAC), due to immunoglobulin E (IgE)–mediated mast cell and histamine-related inflammation, to the clinically more severe diseases associated with T cell–mediated chronic inflammation, vernal and atopic keratoconjunctivitis (VKC, AKC). The ocular allergic responses in SAC and PAC are confined to the conjunctival tissues, whereas in both VKC and AKC the cornea also can become involved, potentially leading to impaired vision. Research to identify the inflammatory cells and molecules involved in allergic responses at the ocular surface and their role in the pathogenesis of allergic eye diseases has increased in the past few years. Extensive immunohistochemical studies have identified distinct expression profiles of adhesion molecules, chemokine receptors, cytokines, and immune cell types for each subtype of allergic conjunctivitis, while immune pathways are being studied via novel experimental models. This chapter reviews recent advances in our understanding of the cellular and molecular processes occurring in ocular allergy.

KEY CONCEPTS

Predominating Cell Types in the Conjunctival Tissues

In seasonal and perennial allergic conjunctivitis: mast cells
In vernal keratoconjunctivitis: eosinophils, T cells, neutrophils, mast cells
In atopic keratoconjunctivitis: T cells, eosinophils, neutrophils

SEASONAL ALLERGIC CONJUNCTIVITIS

Ocular allergy, principally SAC, is the commonest ocular disorder seen in primary care. SAC is a recurrent conjunctivitis apparent only during the pollen season; the timing (spring, summer, or autumn) is dependent on which particular pollen or mold is allergenic for that individual. The disorder can occur at any age but is more frequently seen in children and young adults and tends to lessen in severity in the older age groups.

Patients present with seasonally recurring itching, watering, redness, and swelling of the eyes and lids, and there may be increased conjunctival discharge. An associated rhinitis is common. A personal or family history of atopy very often can be elicited. During the allergen season, the ocular signs range from mild to dramatic and are usually bilateral and symmetrical. Edema of the lids and conjunctiva may be mild and often outweighs the degree of hyperemia, giving a milky or pink appearance to the eye, but the swelling may be gross, with inability to open the lids and a ballooning out of the conjunctiva termed *chemosis,* particularly after exposure to high aeroallergen concentrations or after rubbing of the eye. Eversion of the lids to reveal the tarsal conjunctiva demonstrates some hyperemia and mild infiltration (loss of transparency and thickening) of the conjunctiva with diffuse small inflammatory excrescences known as papillae. Because there is no serious limbal disease or conjunctival scarring and the cornea is not involved, the visual acuity remains normal. Outside the pollen season, the eye examination is normal.

Conjunctival Immunostaining in SAC

SAC involves an immediate, rapid early-phase hypersensitivity response due to allergens binding and cross-linking IgE molecules attached to tissue mast cells. The acute response is rapid, usually taking place within 30 min. The late-phase response occurs 6–12 h after antigen exposure and involves the infiltration of inflammatory cells, primarily mast cells, and some eosinophils and neutrophils (Fig. 47.1).[1] Primarily mast cells and their degranulation products (histamine, proteases, leukotrienes, chemokines, and cytokines) orchestrate the inflammatory response in SAC, although neutrophils and eosinophils also secrete a wide range of proinflammatory mediators that amplify the inflammation. Immunohistochemical studies of tarsal and bulbar conjunctival biopsy specimens demonstrated increased expression of intercellular adhesion molecule (ICAM)-1 and E-selectin adhesion molecules in SAC in comparison with controls, but only inseason,[2] and expression returns to baseline outside the pollen season. This pattern of expression is correlated with the degree of neutrophil or eosinophil infiltration in the bulbar tissue, suggesting a mast-cell–mediated cell recruitment process.

Therapy

General measures may provide effective relief, particularly when the disease is not severe. Limiting pollen exposure by keeping windows shut and remaining indoors, especially on high-pollen-count days, is common sense. Cold compresses and ocular lubricants (artificial tears) relieve symptoms, particularly itching.

Numerous classes of agents, both systemic and topical, have been used to manage the signs and symptoms of allergic conjunctivitis.[3] Topical mast cell inhibitors, the prototype being sodium cromoglycate, are the most useful drugs for non-sight-threatening ocular allergy. Sodium cromoglycate eye drops are available over the counter. They have a number of effects (inhibition of other leukocytes, direct mediator antagonism) in addition to inhibiting mast cell degranulation (one of the earliest mechanisms of the acute ocular allergic response), which accounts

for their potency and their ability to offer a preventative action if used early and continued throughout the allergen season. One limitation is the slower onset of symptom relief compared with antihistamines, although this is less of an issue with the newer, high-potency preparations (lodoxamide, nedocromil). They are extremely safe.

If topical mast cell inhibitors do not provide sufficient relief, dual-acting topical antiallergic compounds (olopatadine, epinastine, and ketotifen) combine antihistaminic properties (H1 and/or H2 receptor antagonism) with mast cell stabilization. They offer the advantage of rapid onset of action with the preventative and long-term effect of inhibiting mast cell mediator release. Olopatadine and epinastine in particular offer a clinical advantage over oral and topical antihistamines and compare well with mast cell inhibitors in allergen challenge models and, at least in some studies, in SAC.[4]

Anti-H1/H2 histamine drugs, both oral and topical, are used widely and provide rapid symptom reduction; however, they are not preventative and have limited potency, as they address only one arm of the inflammatory mediator response.[5] Oral antihistamines also treat any rhinitis, but the onset of ocular action is slower, the local effective concentration is less than for topical therapy, and they expose the patient to the risk of unwanted effects. They often are used for children when drop use can be difficult, plus at night any sedative effect can be advantageous. Long-term use of oral antihistamines leads to chronic dry eye. Topical antihistamines are available as higher-potency antihistamine-only preparations (*e.g.,* levocabastine, emedastine, azelastine), which provide rapid onset of symptom relief and more prolonged action after drop instillation. Lower-potency topical antihistamines in combination with a vasoconstrictor (*e.g.,* antazoline-naphazoline) are generally not recommended, especially for long-term use, due to rebound vasodilatation of the conjunctival vessels with long-term vasoconstrictor use. They can cause contact allergic conjunctivitis, sedation, or excitability, and they are slower and shorter-acting than high-potency topical antihistamines.

CLINICAL PEARLS

Seasonal Allergic Conjunctivitis

- Seasonal response to allergen (*e.g.*, pollen)
- Mast cell–mediated
- Antihistamines, mast cell inhibitors

Of the several topical nonsteroidal antiinflammatory drugs (NSAIDs) assessed in ocular allergy, ketorolac is the only one approved for ocular allergy. NSAIDs are not used as first-line therapy for ocular allergy. They offer the advantage of safety, but their efficacy is not well proven against other established remedies, and cost is a concern, as is discomfort upon instillation and potentially reduced patient adherence. The use of NSAIDs is more common outside the United Kingdom.

Topical steroids have a minimal role in SAC because of their potential for ocular adverse effects (see below). They occasionally are used short-term for severe disease to gain control of inflammation, but their use must be supervised by an ophthalmologist.

PERENNIAL ALLERGIC CONJUNCTIVITIS

PAC is the second most common ocular allergy. It bears many similarities to SAC, but because the allergens in PAC are present for most or all of the year, the time course of the disease is not seasonal. The disorder is again most severe and most frequently seen in children and young adults. House dust mite (*Dermatophagoides pteronyssinus*) is the most common sensitizing allergen, but animal hair and dander, molds, and other antigens may be responsible.

The symptoms are perennial ocular itch, discomfort, watering, redness, and some discharge. Patients may be able to correlate symptomatology with exposure to, for example, pets or a particular location. House dust mite allergy sufferers may give a history of symptoms worse in the morning. Approximately one-third have an associated rhinitis, and a family and/or personal atopic history is very common. The clinical appearance is of mild conjunctival inflammation, and clinical signs may be very slight. The bulbar conjunctiva (on the eye globe) may be slightly red and edematous, and the tarsal conjunctiva shows mild to moderate hyperemia, infiltration, and fine papillae. Lid edema is usually mild. As with SAC, there is neither conjunctival scarring nor corneal or serious limbal involvement, so normal visual acuity is maintained.

Immunohistological Studies in PAC

As with SAC, PAC involves an immediate-type hypersensitivity response, but because the allergens are present continuously, the resultant inflammation is more chronic. Therefore the immunopathology of PAC differs slightly from that of SAC. Increased numbers of mast cells are detected in both the tarsal conjunctival epithelium and the substantia propria, with both mucosal and connective-tissue-type mast cell phenotypes.[2] In addition, mast cells, eosinophils, neutrophils, and T cells are present, suggesting that several cell-mediated processes are involved and contribute to the chronic inflammation found in PAC.[7]

Therapy

In the case of house dust mite sensitivity, advice should be provided on mite reduction; allergy support groups can be helpful for this and for accessing equipment. Potential mite reduction measures include removing soft furnishings (*e.g.*, carpet, curtains) from the bedroom; using special vacuum cleaner filters; intensive and regular vacuuming of bedrooms, including the curtains and mattress; using a mite-impermeable mattress and pillow covers; washing bed linen and curtains at mitocidal temperatures (>131 °F or >55 °C); and using mitocidal chemicals. For mold sensitivity, dehumidifying devices and mold-killing chemicals may help.

The drug therapy of PAC is essentially as recommended for SAC (see above), but as the disease is usually prolonged, the continuing use of mast cell inhibitors assumes more importance, whereas antihistamines tend to be used intermittently for flare-ups of inflammation.

Allergen-specific immunotherapy (AIT) can be effective for patients with severe allergic rhinoconjunctivitis who have specific IgE antibodies to allergens (Chapter 91). Increasing doses of the allergen are administered by subcutaneous immunotherapy (SCIT) or sublingual immunotherapy to achieve hyposensitization mediated by production of interleukin (IL)-10 and transforming growth factor (TGF)-β1. Side effects, including anaphylaxis, are known to occur with this form of therapy. SIT requires a long-term commitment from the patient and/or caregiver in terms of time (SCIT requires monthly injections for 3 years) and expense. This may not be practical for the SAC or PAC patient who does not suffer from other comorbidities.[8]

Experimental Models of Allergic Conjunctivitis

Conjunctival Allergen Challenge

This model involves challenging the ocular surface with an allergen to artificially provoke an ocular allergic response in sensitized individuals.[9] Symptoms are similar to those seen in SAC, and so the model is useful for investigating the early- and late-phase allergic responses at the ocular surface. During the early-phase response (20 mins post challenge), increased levels of histamine and tryptase can be detected in tears, suggesting that the active cell population is predominantly mast cells. At 6 hours, histamine and eosinophil cationic protein levels are increased, but not tryptase, suggesting that basophils and eosinophils are infiltrating and active during the late phase.[10] T cells are also increased and can be seen in bulbar biopsy specimens. The allergen challenge model is often used for testing the efficacy of eye drops.

Experimental Allergic Conjunctivitis

A mouse model of experimental allergic conjunctivitis (EAC)[11] was established by an initial footpad sensitization with short ragweed pollen (SRW), followed 7–10 days later by conjunctival SRW challenge. An infiltration of mast cells, neutrophils, and eosinophils occurs, as well as increased conjunctival chemosis and lid edema. Interestingly, although there is no significant infiltration of T cells, expression of the model is attenuated in IL-12 knock-out mice. In BALB/c mice, SRW-induced EAC was interferon (IFN)-γ–dependent and could not be induced in IFN-γ knock-out mice,[12] supporting a role for Th1 pathways. A role for thymic stromal lymphopoietin (TSLP) has also been demonstrated in EAC, with TSLP expression upregulated in allergen-challenged corneal and conjunctival epithelium.[13]

VERNAL KERATOCONJUNCTIVITIS

VKC is a serious ocular allergy of childhood, comprising 0.1–0.5% of ocular disease in the developed world but more common and much more severe in hot, dry countries, especially the Middle East, West Africa, and the Mediterranean. In the United Kingdom, VKC is an unusual, self-limiting, often seasonal ocular allergy that affects children and young adults, especially males (85%) many of whom have a personal or family history of atopy. The link with atopy and seasonality is less clearly defined in cooler climates.

The symptoms are worse in the spring and summer but last all year in severe disease. Patients complain of marked itching, discomfort or pain, photophobia, stringy discharge, blurred vision, and difficulty opening the eyes in the morning. The ocular signs may be very asymmetrical. Conjunctival signs are maximal in the superior tarsal conjunctiva and limbus, and the heavily inflamed lid may droop (ptosis). The conjunctival surfaces are hyperemic, edematous, and infiltrated, and a stringy mucoid discharge is present. The tarsal conjunctiva is densely infiltrated, with papillae that are often giant (>1 mm in diameter, also known as *cobblestone papillae*). The limbus may show discrete swellings or, less often, diffuse hyperemia and infiltration. The presence of small white-chalky deposits (Trantas' dots) is typical of vernal limbitis. In the later stages, fine reticular white scarring may be seen or, in some cases, sclerosing VKC with sclerosis of the upper limbus over 90–120° of arc (from ~10–2 o'clock).

Visual acuity can be affected by involvement of the cornea (keratopathy), which is most marked in the upper third of the cornea due to greater exposure to toxic inflammatory mediators, not mechanical rubbing by the papillae. At its mildest, there is a punctate disturbance of the epithelium, which may coalesce to form a discrete epithelial defect (macroerosion). Deposition of mucus, fibrin, and inflammatory debris can then result in the formation of a shallow oval plaque (or shield) ulcer, which repels the hydrophilic tears and the epithelial healing response (Fig. 47. 2A). Herpetic and bacterial (staphylococcal) corneal infection may occur as a result of impaired cell-mediated immunity in these patients. In the later stages, scarring of the cornea can lead to permanent visual reduction. Complications related to steroid treatment, along with (because of the young age group) sensory-deprivation amblyopia, can contribute to the potential for long-term visual loss.

Immunological Studies in VKC

Several studies have identified innate and adaptive immune cells to be activated during VKC. T lymphocytes and eosinophils predominate, with mast cells, neutrophils, and other cell types infiltrating the conjunctival epithelium and stroma (Fig. 47.1). Studies of tarsal conjunctival tissue specimens have found increased numbers of activated CD4 T cells, mainly localized to the subepithelial layer of the affected tissue, and increased HLA-DR expression compared with normal subjects.[14] There is evidence that dendritic cells migrate to the lymph node to activate T cells using a CCR7-mediated process.[15] Increased numbers of Langerhans cells and activated macrophages ($CD68^+$) have also been observed. Conjunctival T cells, cloned from VKC tissues, have been functionally characterized as T-helper cell-2 (Th2) type, whereas *in situ* hybridization staining demonstrated upregulation of IL-3, IL-4, and IL-5 messenger ribonucleic acids (mRNAs) in VKC in areas of maximum T-cell infiltration, consistent with Th2 cell involvement.[16] Th1 and Th17 cells also can be involved.[17]

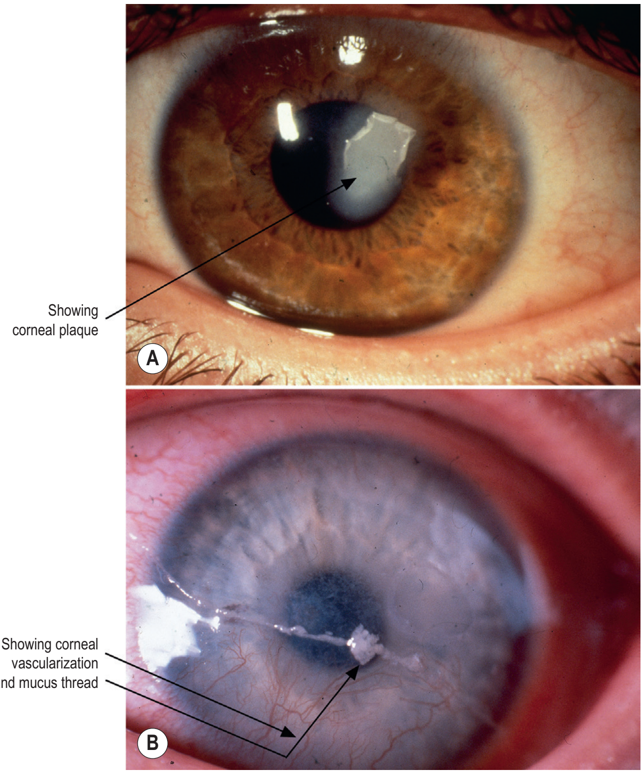

FIG 47.2 Two clinical pictures showing features of (A) vernal keratoconjunctivitis, corneal plaque formation, formation of giant papillae; (B) atopic keratoconjunctivitis, mucus thread, corneal vascularization.

VKC tear fluids were found to have increased levels of IL-4, IL-10, IFNγ, eotaxin, and tumor necrosis factor (TNF)-α compared with controls.[18] Compared with controls, conjunctival biopsy specimens from VKC patients showed increased expression of RANTES, eotaxin, monocyte chemotactic protein (MCP)-1, and MCP-3,[19] reflecting the range of inflammatory cells present.

Tissue remodeling, giant cobblestone papillae formation, limbal stem cell deficiency, and various degrees of superficial corneal opacification are further consequences of the chronic inflammation typical of VKC. Factors that promote fibroblast proliferation include Th2 cytokines, growth factors such as TGF-β, bFGF, PDGF, and also histamine.[20] These growth factors also increase integrin expression, which in turn promotes cellular infiltration and proliferation in VKC. Dendritic cells activating profibrotic T lymphocytes also may be relevant.[21]

Management of VKC

The treatment goals of VKC are to obtain adequate symptom control and to prevent complications of disease and treatment that might permanently reduce visual acuity; one must bear in mind that the disease is likely to remit spontaneously before adulthood. In cases where there appears to be pollen sensitivity, advice on pollen avoidance should be given, similar to that for SAC (see above). Simple measures such as cold compresses, ocular lubricants, and mucolytic drops may help. Oral and topical antihistamines have a very limited role in the disease.

Topical mast cell inhibitors are effective in VKC and should be maintained throughout the time of active inflammation, two to four times daily, depending on the severity of disease and which preparation is used. Olopatadine twice daily is effective and safe to use in VKC. Lodoxamide and nedocromil are more potent than sodium cromoglycate and are worth trying if olopatadine does not appear to control symptoms. Those with mild disease may be able to discontinue therapy during the winter months. It is important to emphasize to patients and parents that mast cell inhibitors are safe and must be continued when using steroids to minimize the dose of steroids required and the risk of steroid complications.

CLINICAL PEARLS

Vernal Keratoconjunctivitis

- Chronic conjunctival inflammation with seasonal exacerbations
- Eosinophils and T-helper 2 (Th2) cells infiltrate the conjunctival tissues
- Usually affects young males
- Cornea can be affected
- Increased expression of Th2 cytokines, adhesion molecules, eotaxin
- Often requires steroids and topical cyclosporine

Steroids are highly potent controllers of multiple features of allergic inflammation and are frequently required in VKC. Unfortunately they carry a significant risk of ocular adverse effects, including ocular hypertension, glaucoma, and cataract, and they can worsen infective keratitis. This is a particular concern in children, where examination to detect these complications can be difficult (*e.g.*, tonometry for intraocular pressure) and also where iatrogenic adverse effects may have long-term visual consequences beyond the time when the disease has spontaneously regressed. To minimize the risk of adverse effects, topical cyclosporine should be used, and then steroids can be prescribed in short, sharp, rapidly tapering doses during episodes of high disease activity or significant keratopathy. In addition, the use of surface-acting preparations with a reduced intraocular action (*e.g.*, fluorometholone, rimexolone, loteprednol) is advisable, although they are not available in preservative-free formulations that are preferred for high-frequency use. Systemic steroids also are sometimes used but expose the patient to numerous potential adverse effects. Supratarsal injections of steroids, either long-acting (triamcinolone) or short-acting (*e.g.*, dexamethasone), may also be used to great effect, but these are not surface-acting agents and therefore do carry significant risk of local side effects; unlike drops, neither the treatment effect nor any adverse effects can be terminated suddenly if problems arise.

Cyclosporine is a specific T-cell inhibitor but also has a number of other inhibitory effects (*e.g.*, on eosinophils, mast cells) that are likely to contribute to its effectiveness in ocular allergic therapy. Topical cyclosporine 2% dissolved in oil (usually corn) has been used to great effect in VKC and is particularly effective in treating corneal complications and in acting as a steroid-sparing agent.[22] It has no systemic adverse effects and none of the serious ocular complications of steroids, so generally it can be used safely long-term. Commercially available topical cyclosporine 0.1% in a cationic emulsion (Ikervis in UK; Restasis in US) has recently been licensed for use in dry eye. A randomized study in Europe evaluating 4×/day topical cyclosporine 0.1% in children with VKC is ongoing.

Surgical interventions are sometimes required in VKC for the corneal manifestations; surgical or excimer laser superficial keratectomy may be used in conjunction with medical therapy for plaque ulcer; rarely, corneal grafting may be required for scarring. Surgical removal of giant papillae or conjunctival reconstruction is not generally recommended.

Experimental Model of VKC

In genetically susceptible rats and mice, experimental blepharoconjunctivitis (EBC) is inducible by subcutaneous immunization with SRW followed by conjunctival allergen challenge at day 10. In this model a significant eosinophilia is found 24 hours after challenge, and EBC has therefore been used as a model for studying eosinophil infiltration as found in VKC. It also can be induced by adoptively transferring Th2, but not Th1, T cells, consistent with our understanding that eosinophil infiltration is Th2-mediated.[23]

ATOPIC KERATOCONJUNCTIVITIS

AKC is the least common but most serious of the ocular allergies. It is a life-long condition that affects adults who have systemic atopic disease, particularly atopic dermatitis. It usually starts in the late teens, but unlike VKC, the disease is persistent and may be relentlessly progressive; occasionally the disease can begin in childhood. AKC is a highly symptomatic disorder with severe itching, pain, watering, stickiness, and redness of the eyelids and eye.[24]

CLINICAL PEARLS

Atopic Keratoconjunctivitis

- The most severe form of allergic eye disease
- Affects adults with atopic dermatitis or asthma
- Predominant infiltration of T cells expressing interferon (IFN)γ in severe cases
- Cornea can be affected, often due to secondary infections
- Requires steroids and cyclosporine

There is usually facial atopic dermatitis involving the eyelids. The lid margins show severe blepharitis (chronic inflammation of the lash follicles and Meibomian glands) and are thickened and hyperemic, posteriorly rounded, and sometimes keratinized; the lid anatomy may be distorted with ectropion (outwardly turning eyelid), entropion (inwardly turning eyelid), trichiasis (in-turning lashes), loss of lashes, and notching. The whole conjunctiva is affected and shows intense infiltration, papillae (which may be giant), and sometimes scarring with linear and reticular white scar tissue, lid-to-conjunctiva adhesions (symblepharon), shrinkage or loss of the conjunctival sac, and secondary lid distortion. Marked limbal inflammation can develop, and Trantas' dots may occur. The disease may not affect the cornea at all, in which case it is sometimes called atopic blepharoconjunctivitis (ABC); in this situation, the overall inflammation is generally less severe.

The cornea may be affected directly during inflammation, or it may be damaged secondarily after extensive changes to the protective ocular surface by continual mechanical trauma, reduced lid protection, or severe loss of conjunctival tear production. Significant visual acuity reduction due to corneal involvement occurs in 40–70% of cases. Keratopathy may consist of punctate and macroscopic epithelial defects, filamentary keratitis, plaque ulcer, progressive scarring, neovascularization (with or without lipid deposition), thinning, and secondary corneal infections (herpetic, bacterial, and fungal) (Fig. 47.2B). There are recognized associations between AKC and eye rubbing, keratoconus, atopic cataract, and retinal detachment.

Immunological Studies in AKC

In AKC the predominant cell types infiltrating the conjunctival tissues are T cells, eosinophils, and neutrophils (Fig. 47.1). As observed in VKC, increased numbers of activated CD4 T cells, HLA-DR expression, and cells of the monocyte/macrophage lineage are found in conjunctival biopsy specimens in AKC,[14] as well as mRNA expression of IL-3, IL-4, and IL-5 in the stroma. However, in AKC there is a significant increase in the expression of IL-2 mRNA and in the numbers of IFN-γ–expressing T cells, suggesting a Th1-mediated inflammation in this disease.[16] Collagen deposition and conjunctival tissue remodeling are considerable in VKC and AKC, so the production of proinflammatory cytokines by infiltrating cells may be the mechanism whereby tissue-resident cells such as conjunctival fibroblasts become involved.

Experimental Model of AKC

To investigate the immunopathogenic mechanisms involved during AKC, a new clinically more severe model of EAC has been developed.[25] In this model, EAC was induced in *C57BL/6* mice by systemic immunization and topical daily challenge with ovalbumin (OVA). OVA-challenged mice exhibited more severe clinical symptoms compared with other mouse models described above, with chemosis and hyperemia. Because this model demonstrated clinical symptoms similar to AKC, it has been used to show that mast cell, CD4 T cell, and dendritic cell numbers are increased during disease, while IL-9, a growth factor for mast cells, was also upregulated (Mohd Zaki et al, *submitted;* Fig. 47.3).

Therapy

Therapy for AKC not only aims to control symptoms but also attempts to modify and reduce serious sight-threatening sequelae; therefore it should be aggressive. The topical treatment of the ocular surface is similar to VKC in that some general therapy may help, antihistamines are not useful, mast cell inhibitors are continued long-term, and steroid and cyclosporine drops are often required. However, the disease is generally less episodic than VKC, so long-term steroid use is often needed, and steroid-related complications are more problematic. In particular, herpetic keratitis, which is more common and severe in AKC, can be potentiated by topical steroids. Topical tacrolimus is more potent than topical cyclosporine and well tolerated.[26] Facial and lid dermatitis should be actively managed, if necessary in conjunction with a dermatologist, whereas lid margin inflammation (blepharitis) should be treated with hot compresses followed by lid hygiene, topical antibiotic, and/or steroid preparations and systemic low-dose antibiotics (especially tetracyclines), all of which will lessen the need for antiinflammatory and immunosuppressive therapy.

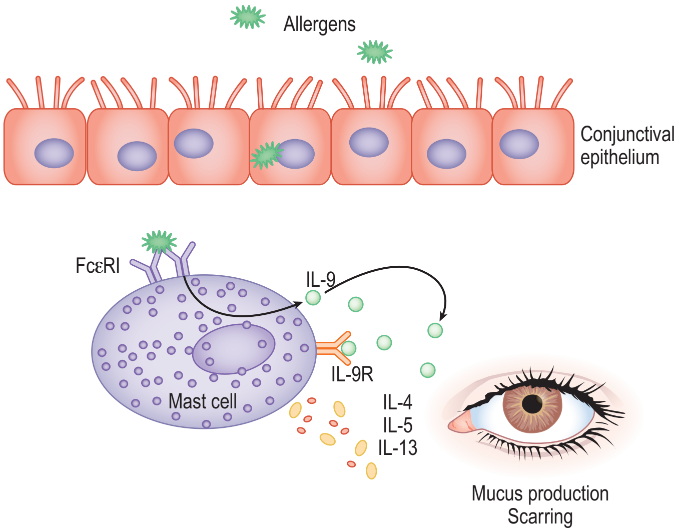

FIG 47.3 Hypothesis of a role for interleukin-9 in allergic conjunctivitis.

Systemic therapy can be necessary in severe cases, particularly when surgical therapy is undertaken, and includes steroids, cyclosporine, and sometimes other immunosuppressive agents such as mycophenolate mofetil. All of these carry risks of serious side effects and also affect the general atopic picture, so consultation with the patient's physician is advisable.

A significant number of patients require ocular surgery, either as a consequence of the disease or because of associated keratoconus. Surgery for AKC includes both elective procedures and emergency interventions and may consist of corneal gluing, patch grafts, corneal transplants (partial or full thickness), conjunctival reconstruction, amniotic membrane grafts, and limbal transplantation. These are generally high-risk procedures and often require support with systemic immunosuppression.

In summary, allergic disorders of the eye range in severity and duration. Recent studies have increased our understanding of the molecular mechanisms involved. VKC and AKC require immunosuppressive therapy, which can have serious side effects. Although the therapeutic options for treating mast cell–mediated forms of allergic conjunctivitis have improved, there is still a need to find alternative, safer therapies for the more severe and chronic forms.

MULTIPLE-CHOICE QUESTIONS

1. Which patient with ocular allergy would you treat with specific immunotherapy?
   A. Seasonal allergic conjunctivitis (SAC)
   B. Perennial allergic conjunctivitis (PAC)
   C. Vernal keratoconjunctivitis (VKC)
   D. Atopic keratoconjunctivitis (AKC)

2. Anti-IgE is indicated in which forms of ocular allergy?
   A. SAC
   B. PAC
   C. VKC
   D. AKC

3. Are topical cyclosporine and/or tacrolimus indicated in ocular allergy?
   A. Yes
   B. No
   C. Unknown

48

Drug Hypersensitivity

Mariana Castells, Rafael Bonamichi-Santos

KEY CONCEPT

Main Presentations of Drug Hypersensitivity

1. Type I reactions with the involvement of mast cells and basophil triggering by IgE and/or non-IgE mechanisms and ranging from urticaria to anaphylaxis
2. Type IV delayed hypersensitivity reaction presenting as delayed rash; drug-specific T cell–specific clones may be identifiable
3. Severe cutaneous reactions, including Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), drug-induced reactions with eosinophilia and systemic symptoms (DRESS), and acute generalized exanthematous pustulosis (AGEP), in which HLA genotypes and viral infections play major roles

Reactions to drugs are an important source of morbidity and mortality and constitute a major hazard in the practice of medicine. We have an incomplete understanding of the mechanisms of the reactions, few tools for their diagnosis and/or prevention, and limited treatment options.[1,2] With the introduction of new and better medications to treat cancer, chronic inflammatory diseases, and infections, there has been a parallel increase in instances of drug allergy and hypersensitivity. Although these new, targeted therapies offer increased survival and quality of life, repeated exposures to small molecules and monoclonal antibodies (mAbs) with immunogenic and allergenic capacity have increased the rate of sensitizations and reactions. Drug hypersensitivity prevents patients from receiving first-line therapy, and doctors have few guidelines on how to diagnose and address these potentially life-threatening reactions.[3,4]

Identifying drug-hypersensitive patients protects them from reexposure to culprit medications and permits access to desensitization procedures when needed and indicated. Identifying patients who are not in fact hypersensitive means they can avoid receiving second-line therapies with their associated increased costs and resource requirements.[5] The vast majority of patients with a history of penicillin allergy have negative results on skin testing and do not react during a challenge or during further courses of penicillin,[6] but there is a lack of standardized reagents approved by the US Food and Drug Administration (FDA) for the diagnosis of allergy to the majority of antibiotics and other drugs. Central to the evaluation of patients with drug hypersensitivity is an understanding of the pathophysiology of the reactions. Genotype studies of patients with severe hypersensitivity reactions, including drug-induced reactions with eosinophilia and systemic symptoms (DRESS), Stevens-Johnson syndrome (SJS), toxic epidermal necrolysis (TEN), have uncovered predisposing specific HLA alleles permitting identification of targeted populations and protection against these reactions.[7] Systematic utilization of available markers of immune cell activation, such as tryptase (the major mast cell protease release during anaphylactic IgE- and non-IgE–mediated reactions) can provide useful diagnostic information and help guide the treatment and management of drug reactions.[8]

EPIDEMIOLOGY OF DRUG HYPERSENSITIVITY

Drug hypersensitivity has a spectrum of presentations and can be fatal[9]: the most common presentation is skin rashes, observed in about 2–3% of hospitalized patients.[10,11] Any drug can elicit hypersensitivity reactions: antibiotics, chemotherapy drugs, mAbs, antihypertensives, radio contrast media, and antiepileptics are among the most frequent causes.[11] The risk of sensitization and of a reaction depends on the drug chemistry and structure, the host immune system, the dose, the route, the duration of treatment, the patient's gender and specific HLA alleles. In a study from Brazil, >50% of the anaphylactic reactions treated in the emergency department were induced by nonsteroidal anti-inflammatory drugs (NSAIDs), the most frequently implicated medications.[12] A recent US study of drug-induced anaphylaxis found that most patients were female, few received appropriate treatment with epinephrine, and 29% had concomitant asthma and allergic rhinitis. A high proportion of these patients were receiving antidepressants, angiotensin-converting enzyme (ACE) inhibitors and/or angiotensin II blockers, confirming the association of these medications with severe reactions.[13]

IMMUNE DRUG RECOGNITION AND GENETIC BASIS OF DRUG HYPERSENSITIVITY

Drugs are recognized by the immune system and initiate immune responses, depending on their structure, size, and multimeric/multivalent presentation. Most drugs are small molecules, which require haptenization, or binding to carrier proteins, to interact with antigen-presenting cells (APCs), including B cells. Once B cells are activated, epitope-specific antibodies are made, including IgE if interleukin-4 (IL-4) is present.[14] Beta-lactam antibiotics, such as penicillin and cephalosporins, are haptens with unstable beta-lactam rings that acylate lysine residues in proteins, forming covalent bonds and leading to the major penicilloyl epitope responsible for urticarial reactions. Carboxyl and thiol groups in beta-lactams can also haptenate. These hapten–carrier complexes are called *minor allergens* because they are found in only a small proportion of cases; they have been implicated in anaphylactic IgE-mediated reactions to penicillin.[15] Large molecules, such as succinylcholine, which has quaternary ammonium epitopes, can act as complete allergens. Epitope-specific antibodies can elicit type I, II, and III hypersensitivity reactions (see below). Type IV (T cell–mediated) reactions can occur through several mechanisms. Currently at least three models are proposed—the hapten/prohapten model, the p-I model, and the altered peptide repertoire model (Fig. 48.1).[16] Drugs or their reactive metabolites undergo intracellular processing to generate a pool of peptides, which then are presented in the context of MHC as foreign peptides at the surface of the APC and elicit a T-cell response (see Fig. 48.1A). The three current models for T-cell interactions with small drugs are shown in Fig. 48.1B. The prohapten/hapten model is based on the drug binding to a protein for processing and generating haptenated peptides recognized by T cells as neoantigens. In the p-I model, small drug molecules bind directly to the HLA molecule or T-cell receptor (TCR) in a noncovalent manner and stimulate T cells. In the altered repertoire model, small molecules bind directly to the MHC-binding cleft to alter the specificity of peptide binding. This results in the presentation of novel peptide ligands that elicit an immune response. Fig. 48.1C shows the altered repertoire model in the case of abacavir (green), which binds to HLA-B*57:01 (gray). The neoepitopes generated by abacavir are thought to be responsible for T-cell activation and the symptoms of hypersensitivity.

At least 24 HLA alleles have been identified in association with drug hypersensitivity, providing an insight into both the complexity of the immune response to drugs and our incomplete

FIG 48.1 Models of T-cell activation by small molecules. (A) Peptide selection and presentation by MHC. (B) Mechanisms of T-cell activation by small molecules. (C) The abacavir–HLA-B*57:01 interaction demonstrates the altered peptide repertoire model. (From White KD, et al. Evolving models of the immunopathogenesis of T cell-mediated drug allergy: the role of host, pathogens, and drug response. *J Allergy Clin Immunol.* 2015; 136: 219–34.)

understanding of the pathogenesis of these reactions.[17] Although different organ systems are affected, typically the targets are the liver and skin; other organs, such as muscles (statin-induced myopathy) and neutrophils (clozapine-induced agranulocytosis), can be affected, indicating a heterogeneity determined not just by the associated HLA allele but also by the expression of homing receptors and T-cell clonotypes.[16] Striking ethnic variations, such as the high prevalence of HLA-B*15:02 in carbamazepine-induced SJS/ TEN have been uncovered in Han Chinese, Thai, and Malay populations, but not in Japanese, Korean, or Northern Europeans (Table 48.1). Some HLA alleles are associated with reactions to unrelated compounds, such as B*57:01, which has been linked to reactions to abacavir and flucloxacillin, with different organ target effects. In contrast, specific HLA alleles may predispose to a particular type of organ injury regardless of the drug involved in the reaction, as seen with HLA-DRB1*15:01–associated liver injury with lumiracoxib and co-amoxiclav. Although HLA-associated reactions occur within hours to days of drug exposure, additional factors must influence these interactions because rechallenge with the drug may not reproduce the symptoms, and time lags have been observed. Such factors can be influenced by the dose. High doses of phenytoin can increase the rate of cutaneous eruptions, which suggests that genetic polymorphisms influence drug metabolic pathways leading to a potential increase in the risk for idiosyncratic reactions. A recent genome-wide association study has linked phenytoin reactions to allelic variations of cytochrome P450 isoform CYP2D9*3, with resulting decreased detoxification activity of CYP2C9.[18] Evidence for the association of specific HLA alleles in penicillin/beta-lactam or sulfonamide reactions is less clear, perhaps because these medications are metabolized into several antigenic and allergenic components that interact with multiple HLA types. The recently reported association between penicillin-induced type I reactions and HLA-DRA indicates the need for strong phenotype association with the culprit drug and adequate sample size.[19] The strength of the association between HLA alleles and certain drug reactions can be very strong, as seen with abacavir and HLA-B*57:01. Patients expressing the relevant allele can be patch tested before exposure to the drug. Prospective DNA screening has a 100% negative predictive value, eliminating all potential reactors.

RISK FACTOR FOR DRUG ALLERGY: HOST, PATHOGENS, AND DRUG RESPONSE

Females are at higher risk for drug reactions, but the basis of this propensity has not been studied.[20] Quaternary ammonium compounds present in cosmetics are thought to be cross-reactive with neuromuscular-blocking agents and may increase the risk of drug reactions during general anesthesia. Patients with cystic fibrosis and those with multiple exposures to latex during surgery were found to have latex IgE sensitization and presented severe reactions, including asthma and anaphylaxis. Decrease in aerosolized latex particles has effectively decreased reactions.[21] Because patients with cystic fibrosis have recurrent infections, these patients have an increased exposure to antibiotics and an increased rate of type I IgE-mediated reactions,[22] including anaphylaxis. Increased rates of drug reaction have been observed in patients with human immunodeficiency virus (HIV) infection, especially to trimethoprim-sulfamethoxazole. Low CD4 T cell counts as well as active immune suppression as a result of antiretroviral therapy are thought to increase the risk of reactions.

Heterologous responses to viral infections, in the context of specific HLA alleles, have been implicated in severe skin reactions. T cell–mediated immunity can be modified by heterologous immune responses that are induced by pathogen-specific T-effector-memory cells. Microbial pathogens, such as human herpes virus (HHV) and cytomegalovirus (CMV), among others, can establish lifelong infections and cellular latency. From time to time, latent virus can activate transcriptional programs, resulting in viral proteins that stimulate virus-specific T-cell memory.

The induction of this type of drug hypersensitivity requires an HLA risk allele, a primary infection with HHV or other viruses in the context of that HLA risk allele, polyclonal expansion of CD8 T cells, and the induction of memory T cells. Upon exposure to the drug, the interaction with HLA induces neoantigens, and the peptide–MHC complex is recognized by the TCR, triggering activation of T cells (Fig. 48.2).[16]

About 25% of women who are treated with carboplatin for gynecological cancers become sensitized after several exposures and then have type I IgE-mediated reactions, most of which are anaphylactic. Although carboplatin triggers cell death at the cancer tissue level, it can also bind to proteins as a hapten and then be presented to T cells, inducing sensitization and expansion of B cells producing IgE that recognizes the hapten. Because women with *BRCA1* and *BRCA2* mutations seem more prone to carboplatin reactions after fewer exposures,[23] it is possible that these genetic mutations facilitate T-cell presentation. The presence of IgE antibodies in carboplatin-sensitized women can be detected in blood and by skin test. The IgE levels may be transient, being lost within 6–12 months of exposure. However, memory T and B cells remain active in these patients, allowing clonal expansion upon reexposure months to years later. Patients with connective tissue disorders have an increased rate of reactivity to mAbs.[24] Similarly, women exposed to endogenous and exogenous progesterone can develop progesterone hypersensitivity.[25]

CLASSIFICATION OF DRUG HYPERSENSITIVITY REACTIONS

Drug reactions can be classified according to whether they occur as a result of the mode of action (on target) or in some other way (off target) (Fig. 48.3).[16] Type A (on-target) reactions account for over 80% of drug reactions. These are predictable, dose dependent, and mirror the pharmacological action of the drug. Type B (off-target) reactions comprise 20% of drug reactions. These are not predictable and may be immunological or nonimmunological. Immunological reactions include B cell–dependent reactions, such as antibody-mediated immediate and immune complex reactions (Gell and Coombs types I and III) and T cell–mediated reactions (type IV). Nonimmunological hypersensitivity reactions include idiosyncratic reactions caused by individual predisposition (*e.g.*, enzymatic defect) and activation of effector cells through off-target receptors, such as the MRGPRX2 mast-cell receptor, a transmembrane G-coupled protein that can be activated by quinolone medications, such as icatibant, and neuromuscular blocking agents, such as atracurium.[26]

Drug hypersensitivity can cause a spectrum of hypersensitivity diseases. These were originally classified by Gell and Coombs into four types: antibody-dependent type I, II and III reactions and T cell–mediated type IV reactions. More recently, in the light of developments in T-cell biology and to take account of

TABLE 48.1 HLA–Associated Drug Hypersensitivity Reactions

Drug	Adverse Drug Reaction	Associated HLA Alleles	Positive Predictive Value	Negative Predictive Value	Populations
Abacavir	HSS	B*57:01	55%	100%	European, African
Carbamazepine	SJS/TEN	B*15:02	3%	100%	Han Chinese, Thai, Malaysian, Indian

FIG 48.3 Adverse drug reactions can result from either on-target or off-target interactions between the drug and cellular components. (From White KD, et al. Evolving models of the immunopathogenesis of T cell-mediated drug allergy: the role of host, pathogens, and drug response. *J Allergy Clin Immunol.* 2015; 136: 219–34.)

the varied presentation and heterogeneity of T cell–mediated reactions, type IV reactions have been divided into four phenotypes: types IV a, b, c, and d.[27] Because the maturation of B cells and expansion to plasma cells producing Igs depend on the interaction of B cells with T cells in the presence of cytokines and costimulatory molecules, drugs can induce IgE and IgG antibodies and induce type I and type IV reactions in the same patient (Fig. 48.4). Type I reactions result from the release of inflammatory mediators from mast cells and basophils and often present with urticarial (see Fig. 48.4A) and systemic reactions, such as anaphylaxis.

ANTIBODY-MEDIATED DRUG HYPERSENSITIVITY REACTIONS

Type I IgE-Mediated Hypersensitivity

Drugs with hapten-like features bind to soluble and cell-bound proteins, inducing a humoral response, which can lead to IgE antibodies. Chimeric antibodies bearing foreign determinants can also elicit IgE responses. During the sensitization phase at the initial drug exposure, IgE antibodies are generated; these bind to FcεRIα on mucosal and connective tissue mast cells and blood basophils. B cells mature into IgE-secreting cells when activated by T cells in the presence of IL-4/IL13 and CD40/CD40L. The sensitization phase typically requires several days and patients do not develop reactions during the first exposure. Upon re-exposure, crosslinking of FcεRIα receptors on sensitized mast cells and basophils by polyvalent haptenated drug allergens causes cell activation and degranulation and the release of inflammatory mediators that are responsible for the clinical symptoms. Although IgE is produced in small amounts compared with IgG, most IgE is found on tissue mast cells in different organs, including blood vessel walls, accounting for the systemic nature of reactions when mast cells are activated. Small amounts of drug can induce severe systemic reactions, including anaphylaxis, depending on the patient's sensitization and the amount of specific IgE directed against the drug. The relationship between the amount of IgE and the dose of drug allergen can determine the induction of either cell activation or desensitization, activating inhibitory mechanisms.[28] In this type of reaction, symptoms occur within seconds of parenteral drug administration and within minutes of oral administration; both depend on the mediators released from mast cell and basophil granules. Preformed mediators, such as histamine, tryptase and tumor necrosis factor-α (TNF-α) are released first, prostaglandins (PGs) and leukotrienes (LTs) are generated from membrane arachidonic acid within minutes, and newly generated cytokines are released within hours of the initiation of the reaction. Pruritus, urticaria, and angioedema are followed by gastrointestinal (GI) symptoms, such as nausea, vomiting, and diarrhea; hoarseness; shortness of breath and wheezing; and dizziness, which can occur in rapid succession.[29] In highly sensitized individuals, systemic reactions can occur within minutes after intravenous exposure; hypotension, laryngeal edema, and death have occurred following administration of antibiotics and chemotherapeutic agents as a result of cardiovascular collapse or asphyxia. Although skin is the organ most commonly involved, and itching is a typical sign of the initial reaction, ≈60% of anaphylaxis-related deaths are due to asphyxia. Anaphylaxis is diagnosed when two or more organs are affected, when there is a sudden drop of blood pressure after exposure to a known drug allergen, or when there is laryngeal edema (Table 48.2).[30] Atypical symptoms include pain, which has been reported in patients with anaphylactic reactions to taxanes, oxaliplatin, and mAbs, such as rituximab.[31] The mediators responsible for pain have not been identified within mast cells or basophils. It has been suggested that activation of the kinin pathway generating bradykinins may be responsible.[31] The severity of the reactions is graded according to the extent of the symptoms. Reactions confined to the skin or one organ are considered mild and do not require epinephrine treatment. Reactions that involve two organs or are associated with vital sign changes are considered moderate and severe, respectively, and treatment with epinephrine is recommended.[32] Elevated tryptase levels in blood are found in patients with grade 2 and 3 reactions, indicating the involvement of mast cells. Depending on the magnitude of the reaction, tryptase levels return to baseline, usually within days, but sometimes remain elevated for a few weeks after the reaction.[8] Patients with severe anaphylactic reactions induced by drugs

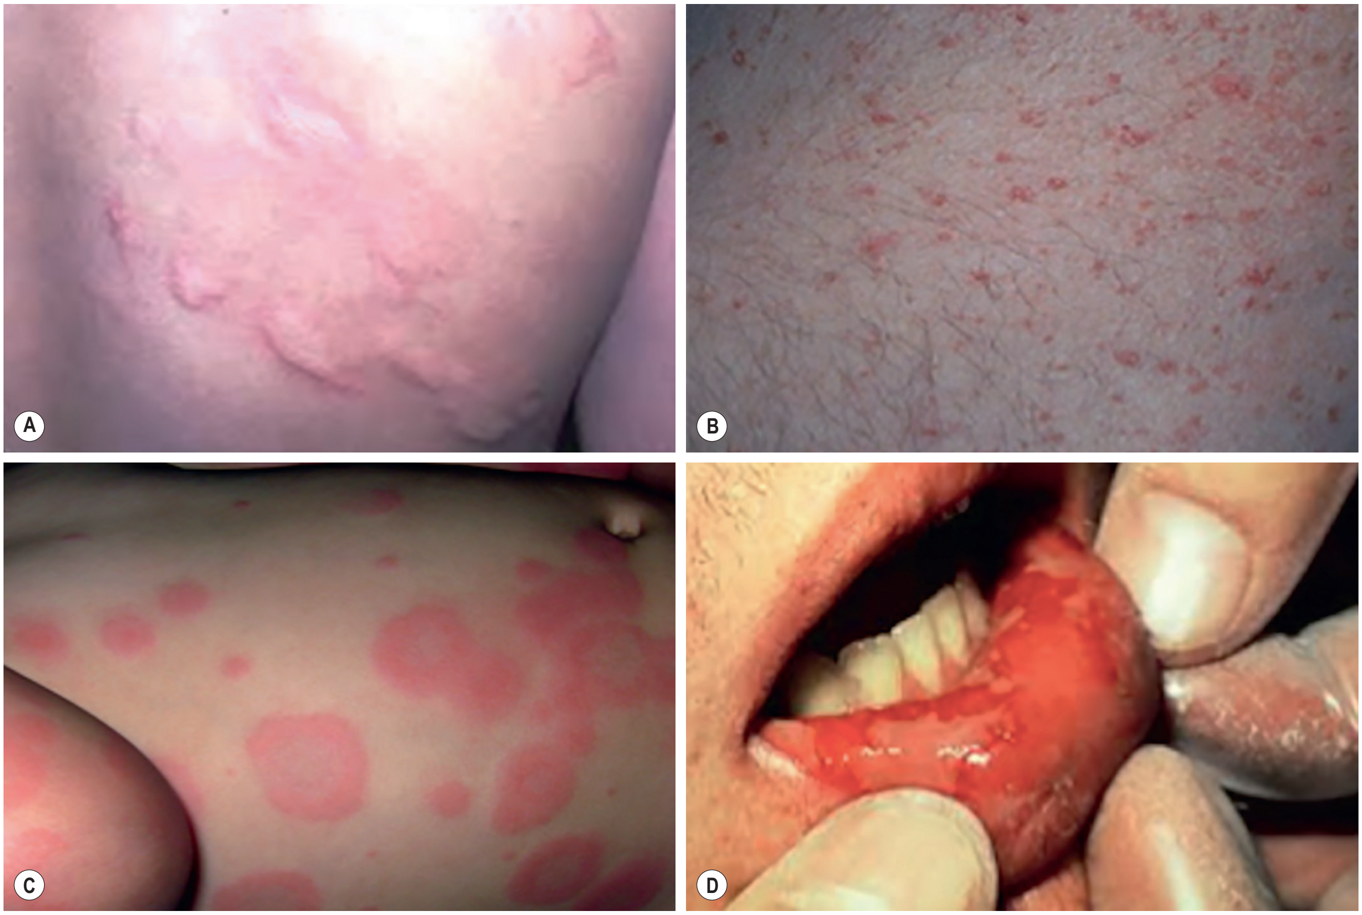

FIG 48.4 Examples of hypersensitivity reactions. (A) Type I: Urticaria. (B) Type IVc: maculopapular rash. (C) Type IVc: erythema multiforme. (D) Type IVc: mucosal involvement (Stevens-Johnson syndrome [SJS])

TABLE 48.2 Severity Grading System of Immediate Type I Hypersensitivity Reactions

Grade	Severity	Description
1	Mild	Symptoms are limited to the skin (*e.g.,* flushing) or involve a single organ/system and are mild (*e.g.,* mild back pain).
2	Moderate	Symptoms involve at least two organs/systems (*e.g.,* flushing and dyspnea), but there is no significant decrease in blood pressure or oxygen saturation.
3	Severe	Symptoms typically involve at least two organs/systems, and there is a significant decrease in blood pressure (systolic ≤90 mm Hg and/or syncope) and/or oxygen saturation (≤92%).

(Adapted from Brown SGA, et al. Clinical features and severity grading of anaphylaxis. J Allergy Clin Immunol. 2004; 114: 371–376.)

should be evaluated for mastocytosis if their tryptase levels do not normalize after the reaction. Common causes of IgE-mediated allergic drug reactions include: beta-lactam antibiotics (penicillins and cephalosporins); chemotherapeutic agents, such as carboplatin, cisplatin, and oxaliplatin; and both chimeric and nonchimeric mAbs.[33] Cross-reactivity occurs with beta-lactam medications; patients sensitized to penicillins can be subject to reactions on first exposure to cephalosporins because these antibiotics share epitopes that can bind beta-lactam–specific IgE. Patients with cancer who are exposed to one platin, such as carboplatin, can react on first exposure to another platin, likely as a result of shared cross-reactive epitopes.[34] Not all patients reacting with symptoms of type I hypersensitivity to taxanes, such as paclitaxel, have evidence of IgE sensitization. Reactions to cremophor, the diluent of paclitaxel, have been implicated in some reactions.[35]

Non–IgE-Mediated Type I Hypersensitivity Reactions

The definition of type I hypersensitivity reactions has been expanded to include reactions with similar symptoms without evidence of IgE. These are caused by the presence of multiple activating receptors on mast cells and basophils. Examples include muscle relaxants and quinolones, which can induce anaphylactic reactions with release of mast cell mediators, including tryptase, without evidence of IgE sensitization,[36] indicating that mechanisms other than IgE-mediated degranulation can trigger these effector cells. One candidate for the receptor involved is the G-coupled receptor MRGPRX2.[26] These reactions were previously called "pseudoallergic reactions." The symptoms are identical to IgE-mediated reactions and include hives, angioedema, respiratory distress, GI symptoms, and hypotension; epinephrine is required if the reactions are moderate or severe. Vancomycin can induce histamine release from mast cells without IgE involvement, in a dose-dependent fashion.

CLINICAL PEARLS

Vancomycin Red Man Syndrome

- Presents as erythema, flushing, rarely hypotension
- Histamine elevated in urine and blood
- Direct mast cell activation and release of histamine
- Can be potentiated by mast cell activation agents (*e.g.,* opioids)
- Treatment: slow infusion, dose reduction, and antihistamines

Type II Reactions: IgG-Mediated Cytotoxic Reactions

Type II and type III reactions result from the formation of complement-fixing IgG antibodies, typically of the IgG1 and IgG3 subclasses, which bind to Fcγ receptors (FcγRI, IIa, and IIIa) on macrophages, natural killer (NK) cells, granulocytes, and platelets, or form immune complexes and interact with complement receptors on these cells. In type II reactions, the antibody is directed against antigens on the cell membrane, or immune complex activation occurs on the cell surface. Both events can lead to cell destruction or sequestration; affected cells include erythrocytes, leukocytes, platelets, and bone marrow precursor cells. The development of type II reactions requires an IgG immune response to a drug hapten–carrier complex after high-dose and prolonged treatment, as is seen in penicillin and cephalosporin reactions, where the reaction is caused by complement fixation. IgM antibodies are sometimes implicated, as well as autoantibodies reactive to the carrier molecule. These immune reactions can persist after cessation of the drug. Another type of type II reaction occurs when the drug or its metabolites adhere to the erythrocyte or platelet surface, creating a new antigenic complex with the cell membrane. Quinine-induced thrombocytopenia occurs when IgG or IgM antibodies react with membrane epitopes, such as GPIIb/IIIa (fibrinogen receptor) or GPIb/IX (von Willebrand factor receptor); this only happens when the drug in present in soluble form.[37] This interaction results in platelet destruction and thrombocytopenia. Similar reactions occur with sulfonamides and quinidine. The antibody-coated cells can be sequestered in the liver and spleen by Fcγ or complement receptor binding. Rarely, intravascular destruction occurs via complement-mediated lysis.

Penicillin, cephalosporins, levodopa, methyldopa, quinidine, and some antiinflammatory drugs can induce hemolytic anemia, which presents with fatigue, pallor, shortness of breath, tachycardia, and dark urine.[38] Direct and indirect Coombs tests are positive, unconjugated levels of bilirubin are elevated, haptoglobin is decreased, and hemoglobinuria is present. Thrombocytopenia can occur with quinine, quinidine, sulfonamide antibiotics, and mAbs.[39] Drug-induced thrombocytopenia usually occurs after 5–8 days of exposure but may occur after a single exposure in a sensitized patient. The typical presentation is petechial hemorrhages in skin and mucosal bleeding, sometimes associated with GI and urinary bleeding. Intracranial bleeding is rare, and the platelet count returns to normal 3–5 days after the drug is discontinued. In heparin-induced thrombocytopenia, FcγRIIa receptors on platelets bind IgG and IgM immune complexes of heparin and platelet factor 4 (PF4), a CXC chemokine usually stored in platelet α-granules. About 50% of patients treated for >7 days with heparin develop antibodies against heparin and PF4. These immune complexes activate platelets, releasing PF4 and causing platelet destruction. Mild thrombocytopenia can occur in up to 5% of patients treated with heparin, and 10% develop paradoxical thrombosis, which can be life-threatening.

Type III Reactions

Immune complexes form during normal immune responses without any clinical consequences. Immune complexes can also be formed during treatment with drugs that form hapten–carrier complexes or with chimeric or humanized proteins, such as mAbs. These immune complexes are typically cleared by binding to the FcγRI or complement receptor CR1 on reticuloendothelial cells. Decreased clearance because of high levels complement defects or aberrant FcγRI function can lead to type III reactions. Recently a low copy number of FcγRIII was shown to be associated with glomerulonephritis. Type III reactions can present as small vessel vasculitis and/or serum sickness. Serum sickness was first described when heterologous serum or foreign serum was used for passive immunization. Antibodies appear in 4–10 days and react with drug antigens, forming soluble circulating immune complexes. These immune complexes capture complement and are deposited in postcapillary venules, attracting leukocytes by interacting with FcγRIII, eventually inducing the release of proteolytic enzymes and tissue damage. Nonprotein drugs, such as cefaclor, trimethoprim-sulfamethoxazole, cephalexin, amoxicillin, NSAIDs, and diuretics, are the most commonly implicated drugs, but these reactions can also occur with protein drugs, such as mAbs.

The incidence of hypersensitivity vasculitis is 10–30 cases per million per year. The presentation can include fever, skin rash, myalgia, arthralgia, and lymphadenopathy. Palpable purpura may be present in legs, with lesions that can coalesce and ulcerate. The GI tract, kidneys, and joints can be affected: the prognosis depends on the extent of systemic involvement. Patients taking systemic steroids may present with a milder form of reaction, with fewer manifestations. Renal biopsy reveals IgA-containing immune complexes, similar to those found in IgA nephropathy.

Type IV Reactions

Cell-mediated reactions are now subdivided on the basis of the cytokines produced by T cells and the type of effector immune cells induced by these cytokines, such as eosinophils and neutrophils.

Type IVa reactions correspond to classic T helper 1 (Th1)–type immune reactions, in which Th1 cells activate macrophages by secreting interferon-γ (IFN-γ) and other cytokines (TNF-α, IL-12). These Th1 cells drive the production of the complement-fixing antibodies involved in types II and III reactions and are costimulators of pro-inflammatory responses, and CD8 T-cell responses. Examples of type IVa reactions include tuberculin reactions, contact dermatitis (with activated CD8 cells) and sarcoidosis (with granuloma formation and monocyte activation).

Type IVb reactions correspond to type 2 immune responses with IL-4, IL-13, and IL-5 cytokines, which promote IgE- and IgG4-producing B cells, mast cells, and eosinophils. IL-5 production leads to eosinophilic inflammation, which is seen in many drug-induced hypersensitivity reactions, including DRESS. Type I reactions are linked to these reactions since IgE is produced as a result of IL-4 and IL-13 secretion by Th2 cells. Maculopapular

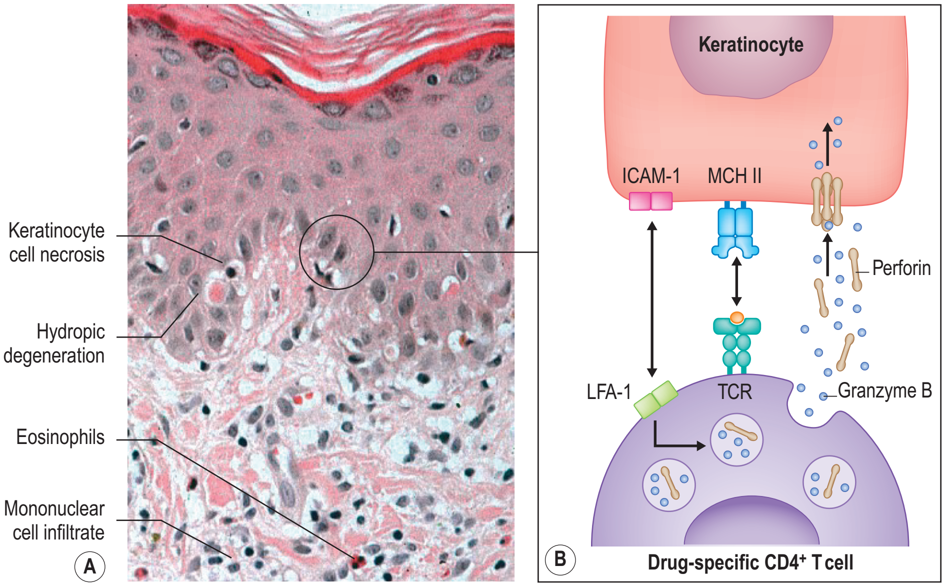

FIG 48.5 (A) Typical histology of a maculopapular exanthema (MPE). Note the focal keratinocyte necrosis, often in close apposition of T cells (which have cytotoxic potential and are perforin-positive). (B) Schematic representation of CD4-mediated killing of activated keratinocytes, which express MHC class II and intercellular adhesion molecule 1 (ICAM1). (Modified from Pichler WJ. Delayed drug hypersensitivity reactions. *Ann Intern Med.* 2003; 139: 683–693.)

exanthema (MPE) (Fig. 48.5), infections with nematodes, asthma, and rhinitis are considered part of this group of reactions.

KEY CONCEPT

Drug-Induced Reactions With Eosinophilia and Systemic Symptoms (DRESS) Syndrome

- Drug-induced
  - Anticonvulsants, antidepressants, non-antimicrobial sulfones/sulfonamides, nonsteroidal antiinflammatory drugs (NSAIDs), angiotensin-converting enzyme (ACE) inhibitors, beta-blockers, and antibiotics
- Systemic disorder
  - Hematological abnormalities (eosinophilia, atypical lymphocytes)
  - Multiorgan involvement
    - kidney, liver, heart, lung, thyroid
  - Hypogammaglobulinemia
  - Lymphadenopathy
  - Skin involvement

Type IVc reactions result from T-cell migration to tissues and direct damage or killing of tissue cells, such as hepatocytes, through perforin-, granzyme B– and Fas-ligand–dependent mechanisms, with the recruitment of other inflammatory cells, such as monocytes, eosinophils, and neutrophil polymorphonuclear leukocytes. These reactions present as delayed hypersensitivity reactions, such as SJS, TEN, and contact dermatitis (Fig. 48.4B, C and D).

Type IVd reactions occur when T cells activate sterile neutrophilic inflammation, as in acute generalized exanthematous pustulosis (AGEP). T cells producing CXCL8 and granulocyte macrophage–colony-stimulating factor (GM-CSF) recruit leukocytes, and the cytokines then prevent their apoptosis. Behçet disease, linear IgA bullous dermatosis, and pustular psoriasis are examples of type IVd reactions (Fig. 48.6).

KEY CONCEPT

Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)

SJS
- Detachment <10% of body surface area (BSA), plus
- Widespread macules or flat atypical target lesions

Overlap SJS-TEN
- Detachment 10–30% of BSA, plus
- Widespread macules or flat atypical target lesions

TEN
- Detachment of >30% of BSA, plus
- Widespread macules or flat atypical target lesions
- Detachment >10% of BSA with large epidermal sheets and without any macules or target lesions

DIAGNOSIS OF DRUG HYPERSENSITIVITY: CLINICAL SYMPTOMS AND HISTORY

A detailed history is the most important element in the diagnosis of all drug reactions; it is necessary to determine the type of reaction and the test required to confirm the diagnosis and to establish management and treatment plans. Type I IgE- and non–IgE-mediated reactions occur with a rapid onset, within minutes of drug exposure, which can present as pure skin manifestations or as involvement of other organs. Sudden onset of hypotension can be the first manifestation during anesthesia or when infusing high doses of chemotherapy drugs, such as taxanes. Tryptase levels help determine the mechanism of the reaction and its extent. The basophil activation test (BAT) has been performed for several drugs yielding different results;

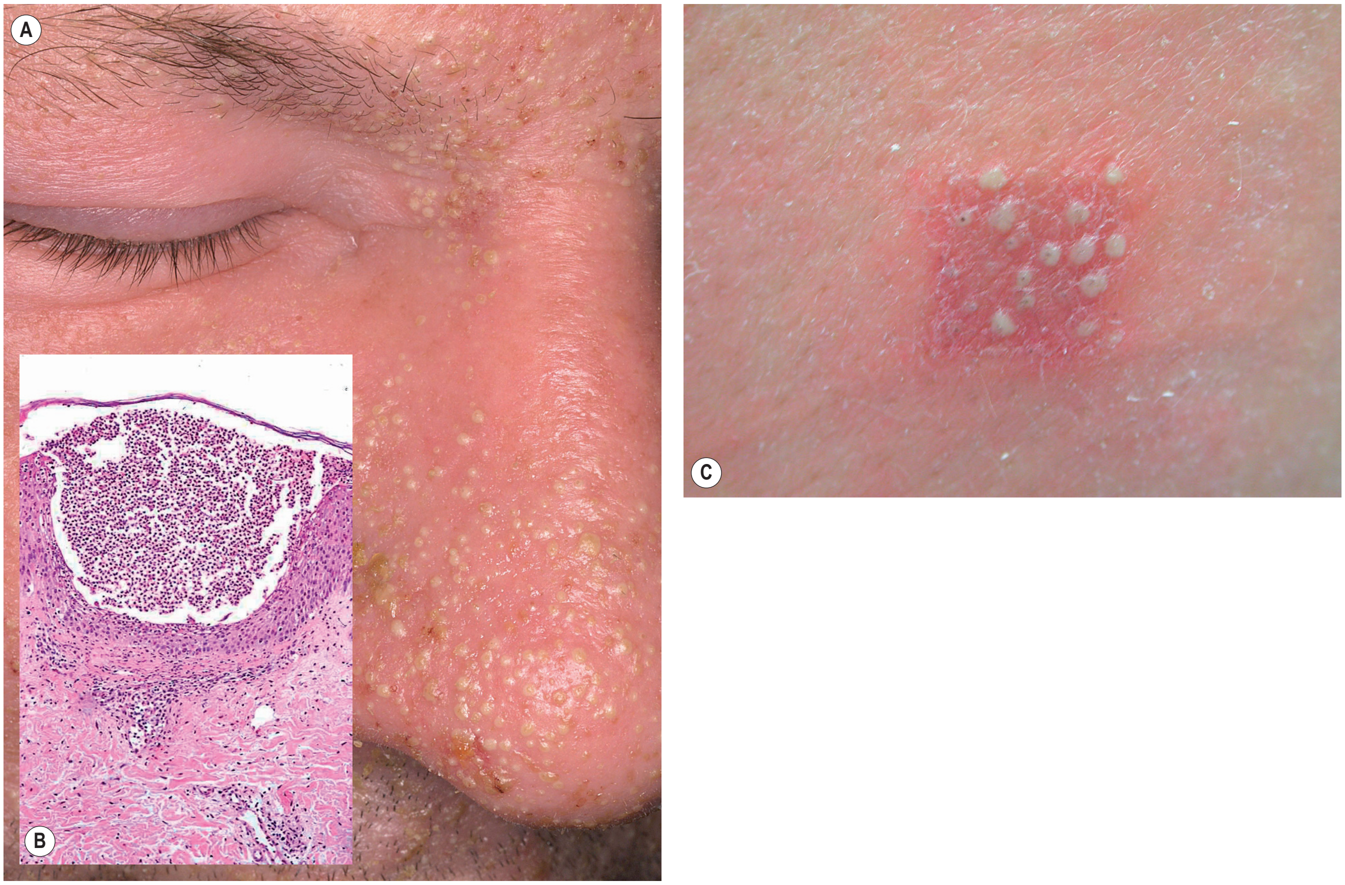

FIG 48.6 Clinical pictures and immunohistologies of drug-induced exanthema. (A) Pustular drug eruption (acute generalized exanthematous pustulosis [AGEP]). (B) Intraepidermal, nonfollicular pustules. (C) A patch test reaction leading to a pustular reaction. (From Schaerli P, Britschgi M, Keller M, et al. Characterization of human T cells that regulate neutrophilic skin inflammation. *J Immunol.* 2004; 173: 2151–8.)

the test is limited by the patient's number of basophils and premedications because basophils undergo apoptosis in the presence of steroids. BAT seems to be a promising test for diagnosis of platin hypersensitivity.

Delayed-type IV reactions are characterized by skin rashes. The differential diagnosis includes viral exanthema, other infections, food allergy, and graft-versus-host reactions. Severe reactions, such as DRESS, SJS, and TEN, are associated with blood eosinophilia, leukocytosis, and biochemical changes, such as elevated liver enzymes. Evidence of systemic involvement should be determined with whole-body skin evaluation, and the presence of fever, lymphadenopathy, and organomegaly should be noted. Nikolsky sign should be elicited because its presence can indicate a severe bullous condition. Danger signs without skin involvement, such as malaise, fever, photophobia, abdominal pain, and alterations in GI and urinary function, can be early signs of severe drug-induced syndromes. Type 1 reactions occur within an hour of exposure, but in patients receiving premedication with antihistamines and steroids, onset of urticaria or hypotension may take several hours. Type IV reactions are typically delayed and appear several hours after drug exposure. However, in highly sensitized individuals, symptoms can occur within 1–2 hours.

Diagnostic tools to identify the culprit drug are limited. They include skin testing and patch testing, but these tests are not standardized and have variable reliability.

Tryptase

Activation of mast cells during type I IgE and non-IgE reactions leads to release of granule mediators, including tryptase, which can be measured in serum. After secretion from tissue mast cells, tryptase requires 30 minutes to reach peripheral blood. Its levels peak in 2–4 hours after an anaphylactic event, but in patients with marked elevations above the normal range (11.4 ng/mL), the levels may remain elevated for >6–8 hours and in extreme cases for several days.

Skin Testing, Specific IgE, and Challenges

Skin testing for penicillin has been available for several years and its predictive value is >97%, meaning that patients with negative skin tests are not at risk for anaphylaxis. Patients sensitive to minor determinants may not be identified by current reagents in the United States because none of the tests for minor determinants has been approved. Skin testing for cephalosporin sensitivity has not been standardized but non-irritant concentrations are available for some of them (Table 48.3) as well as for other antibiotics. The sensitivity and specificity of these tests have geographical differences, possibly because of different rates of exposure. Skin testing to chemotherapy and mAbs can be done when an IgE-mediated reaction is suspected, ideally 2–4 weeks after the reaction to minimize false-negative results caused by natural desensitization. The

TABLE 48.3 Nonirritating Concentrations for 15 Commonly Used Antibiotics

Antimicrobial Drug	Full-Strength Concentration	NIC (as Dilution From Full-Strength Concentration)	No. of Patients Tested
Cefotaxime	100 mg/mL	10^{-1}	25
Cefuroxime	100 mg/mL	10^{-1}	25
Cefazolin	330 mg/mL	10^{-1}	25

Ticarcillin	200 mg/mL	10^{-1}	25
Clindamycin	150 mg/mL	10^{-1}	25
Gentamicin	40 mg/mL	10^{-1}	30
Cotrimoxazole	80 mg/mL	10^{-2}	25
Levofloxacin	25 mg/mL	10^{-3}	25
Erythromycin	50 mg/mL	10^{-3}	25
Azithromycin	100 mg/mL	10^{-4}	30
Nafcillin	250 mg/mL	10^{-4}	25

(From Empedrad R, et al. Nonirritating intradermal skin test concentrations for commonly prescribed antibiotics. *J Allergy Clin Immunol.* 2003; 112: 629–630.)

negative predictive value (NPV) for carboplatin is very high with recent exposure, and patients with negative skin test results do not develop anaphylaxis,[24] but the NPV is not known for most mAbs. In a study of patients who needed to be desensitized to trastuzumab, infliximab, or rituximab, only 13 of 23 patients had positive skin test results.[40]

Drug challenges are considered the gold standard for type I reactions and should be performed to confirm tolerance in all patients with negative skin test results. Such challenges can trigger mild, acute, and/or delayed reactions but are considered extremely safe. Cofactors, such as viral infections, can influence these tests, and a patient with negative results of the skin test and challenge can present a recurrent skin rash if he or she takes the same drug during a viral infection. Patients with a history of mild-to-moderate reactions and a remote history of drug allergy, who have negative skin test results, can be safely challenged without an increased risk of anaphylaxis.[41]

Patch Testing, Delayed Intradermal Reading, and Lymphocyte Transformation Tests

Skin testing with percutaneous and intradermal drug injections can provoke a maculopapular reaction at the site of injection in 24–96 hours, mimicking the systemic reaction induced by the drug. These tests have been used to determine which drugs induce the various type IV reactions, such as MPE.[42] Patch testing, with application of the drug allergens to stripped skin after absorption of superficial T cells and other effector cells, is used to identify drugs responsible for contact dermatitis and other type IV reactions. Commercial reagents are available for common contact allergens and provide high specificity for metal allergies, such as nickel allergy. However, for some diseases, such as MPE, DRESS, and AGEP, the sensitivity is considered low. The lymphocyte transformation test relies on the activation and proliferation of T cells cultured in the presence of drug allergens. Reactivity is measured by ^{3}H-thymidine incorporation after several days in culture,[43] or by enzyme-linked immunospot (ELISPOT), 5(6)-carboxyfluorescein N-hydroxysuccinimidyl ester (CSFE) staining, or CD69 upregulation. These tests may prove valuable in the future but have not yet been standardized.

SPECIFIC DRUG HYPERSENSITIVITY

KEY CONCEPT

Drug Allergy

General Evaluation of Drug Allergy

- **History:** Indication for drug use, association with viral/bacterial infection
- **Physical examination**
- **Blood count/differential, Liver function tests**
- **Serum tryptase**
- **Skin testing**
- **Patch testing/Delayed reading of skin test**
- **Specific IgE, basophil activation test**
- **Genotyping**

Specific Evaluation of Drug Allergy

- **Name** of the drug, ingredients, preservatives
- **First exposure**
- **How long ago** did the reaction occur?
- **Re-exposure:** Has the patient been exposed to the drug or a related drug?
- **Other drugs** administered at the same time
- **Associated narcotics**
- **Symptoms and signs** of the reaction
- **Timing of symptoms** relative to the drug exposure

Underlying Condition for which the Drug was Prescribed

- Similar symptoms unrelated to the drug exposure (urticaria)
- Treatment and response to treatment (epinephrine)
- Timing of resolution

Beta-Lactams

Penicillins, aminopenicillins, and cephalosporins can induce type I, II, III, and IV reactions and are the medications most often implicated in drug hypersensitivity. These drugs are small chemical compounds with a common beta-lactam core and different side chains (Fig. 48.7). Drug antigens are created through hydrolysis when in contact with blood or other proteins. Penicilloyl is the dominant (or major) drug allergen responsible for most type I reactions. Minor components include penilloate and penicilloate, which have been implicated in severe anaphylactic reactions. Patients with a history of suspected penicillin allergy can be evaluated by skin testing with major and minor determinants. Over 90% of individuals with a history of penicillin allergy have no evidence of IgE sensitization and can safely be reexposed to beta-lactams with a very low rate of adverse reaction upon reexposure. This contrasts with chemotherapy drugs, such as carboplatin.[34] Once a patient has experienced a reaction, subsequent reexposure typically induces a reaction. Although both medications are haptens and probably trigger T-cell activation and B-cell expansion to produce IgE antibodies in a similar fashion, there are some important differences. The route of administration of chemotherapy drugs is typically intravenous, the doses are high, and the interval times are short, with repetitive doses administered over few weeks to months. In contrast, beta-lactam antibiotics are used for short periods during acute infections, so memory T and B cells may not be reactivated during reexposure. If taken orally, repeated exposure to beta-lactams may generate tolerance instead of allergy. Patients who have a history of penicillin allergy and are admitted to hospital have increased risks of complications from use of second-line antibiotics, with increased days of hospitalization and health care costs.[5]

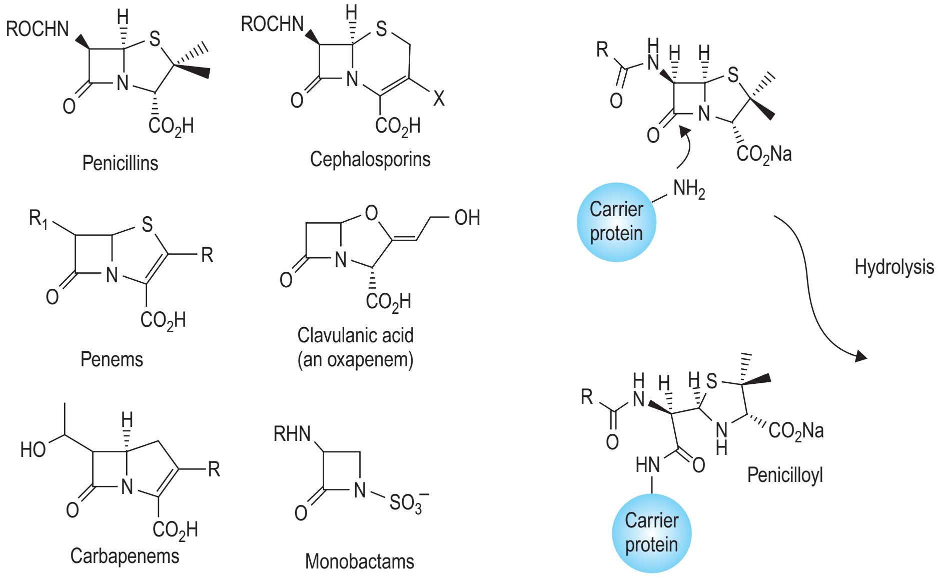

FIG 48.7 Drug antigens: beta-lactams.

The incidence of allergy to specific side-chain epitopes in beta-lactam compounds has increased in the last 20 years as a result of increased use of aminopenicillins and cephalosporins.[44]

Radio Contrast Media

Reactions to iodinated and noniodinated contrast media are relatively rare, and their mechanisms are not well understood, although premedication can protect affected patients. Some of these reactions are thought to be caused by activation of the complement pathway with generation of the anaphylatoxins C3a and C5a, which can bind to complement receptors on mast cells and induce mediator release. The newer nonionic, low-osmolality contrast media products can also be involved in type I reactions; in a few cases, positive skin test results suggest an IgE-dependent mechanism.[45]

Perioperative Anaphylaxis

Patients who have anaphylactic reactions during surgery are at risk for reactions during future operations. Evaluating the drug responsible for these reactions is complex because multiple drugs are used in patients undergoing surgery. Having an accurate account of the initial symptoms of the reaction and changes in vital signs and blood pressure in relation to the timing of each drug used is key to an accurate diagnosis. Neuromuscular-blocking agents, antibiotics, and latex are the most common causes of reactions, with cephalosporins often being implicated. In most cases, skin testing will identify the culprit drug, allowing safe drugs to be chosen for future procedures.[47]

Local Anesthetics

Reactions to local anesthetics are rare, and most are not IgE-mediated. Idiosyncratic reactions include the proarrhythmic effects of lidocaine and other amide drugs. There is no cross-reactivity between benzoic ester and amide drugs, so patients who have reacted to one group generally tolerate drugs from the other group (Table 48.4).

Sulfonamides

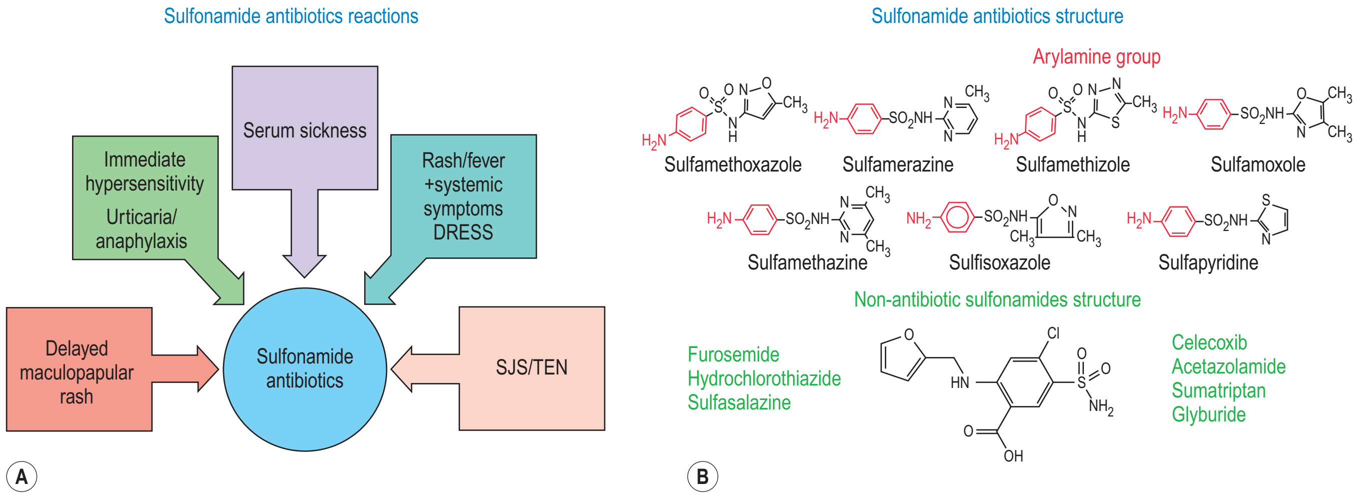
Delayed reactions to sulfonamide antibiotics are common, but all types of reactions have been seen (Fig. 48.8A). Delayed reactions range from benign maculopapular rashes to SJS/TEN. Patients with HIV[47] and cystic fibrosis are at high risk. Sulfamethoxazole metabolism and protein adduct formation stimulates T cells and induces delayed reactions. Nonantibiotic sulfonamides have a similar chemical structure, but their stoichiometry is different because of a shared arylamine group being in a different position.[48] In practice, patients with sulfonamide antibiotic hypersensitivity can be safely exposed to non-antibiotic sulfonamides.[49]

TABLE 48.4 Local Anesthetics

Benzoic Acid Esters	Amides and Other
Benzocaine	Bupivacaine
Butamben picrate	Dibucane
Chloroprocaine	Duclonine
Procaine	Etiodocaine
Proparacaine	Levobupivacaine
Tetracaine	Lidocaine
Cocaine	Mepivacaine
	Prilocaine
	Ropivacaine

Aspirin

Reactions to NSAIDs can induce respiratory and skin reactions as well as anaphylaxis. Up to 10% patients with asthma may have aspirin-exacerbated respiratory disease and react to aspirin and other NSAIDs. They typically have nasal polyps, anosmia, and severe asthma. The pathophysiology of these reactions involves decreased production of PGE_2 and increased production of LTs, which are found in urine and other secretions at baseline and after aspirin challenge. Aggregates of leukocytes and platelets are observed in the peripheral blood of these patients. It is possible that platelets contribute to the pathogenesis of the syndrome. Patients with aspirin-exacerbated respiratory disease (AERD) cannot tolerate any COX-1 inhibitor but can tolerate COX-2 inhibitors indicating a common mechanism of action for all NSAIDs (Fig. 48.9).[50] Urticaria and angioedema can be induced by aspirin and NSAIDs; patients can also present



Sulfonamide antibiotics reactions
Serum sickness
Immediate hypersensitivity
Urticaria/ anaphylaxis
Rash/fever +systemic symptoms DRESS

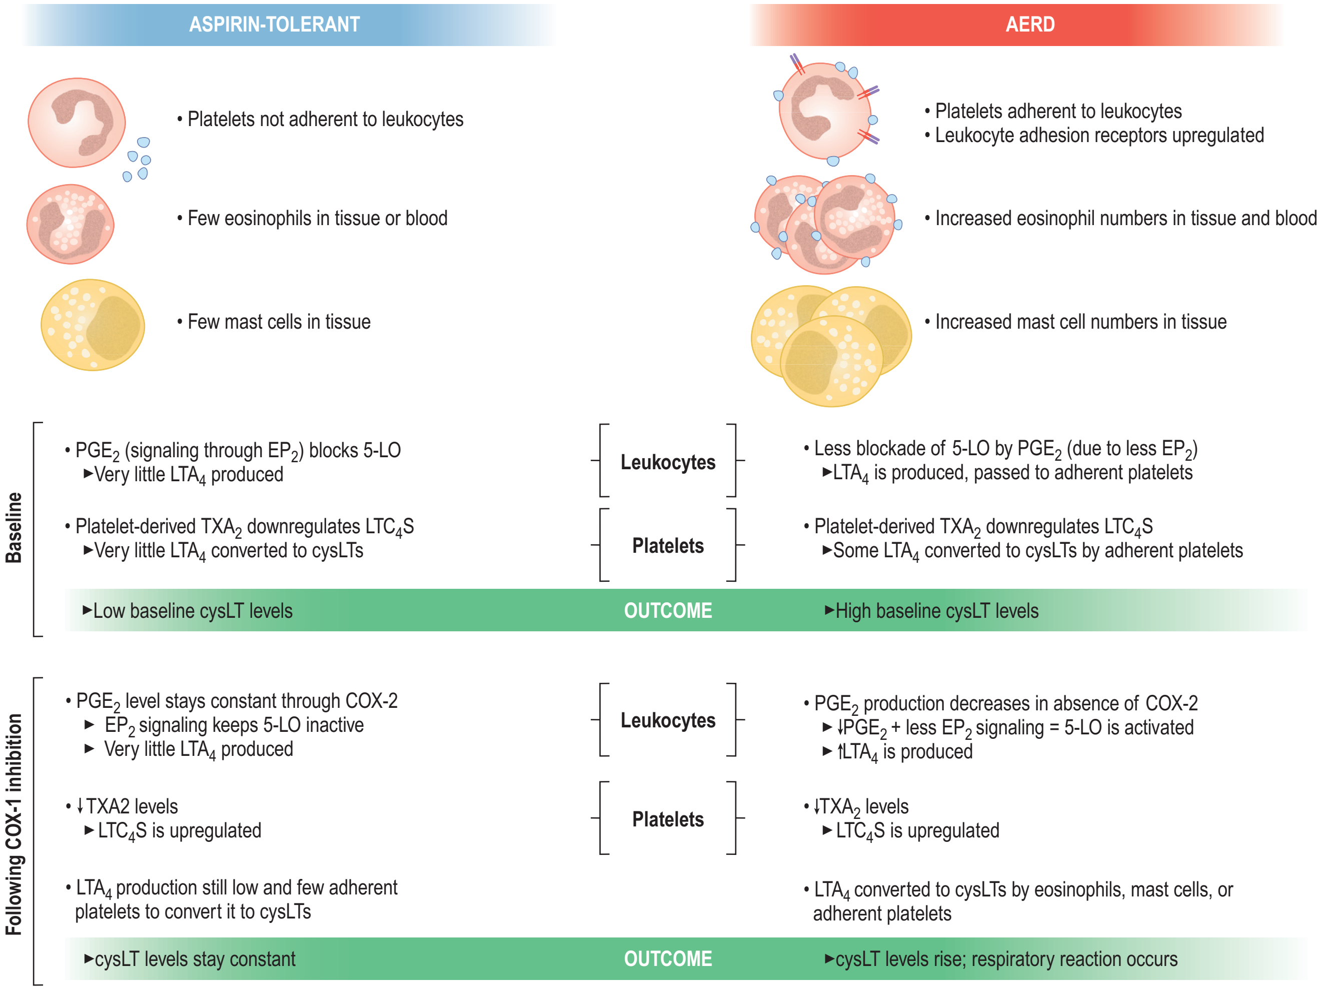
FIG 48.8 Reactions to and structures of sulfonamide antibiotics (A). Structures of sulfonamide antibiotics (B). (Adapted from Tilles, SA, Slatore, CG. Hypersensitivity reactions to non-beta-lactam antibiotics. *Clin Rev Allergy Immunol.* 2003; 24: 221–8.)



ASPIRIN-TOLERANT
AERD
• Platelets not adherent to leukocytes
• Platelets adherent to leukocytes
• Leukocyte adhesion receptors upregulated
• Few eosinophils in tissue or blood
• Increased eosinophil numbers in tissue and blood
• Few mast cells in tissue
• Increased mast cell numbers in tissue
Baseline
• PGE_2 (signaling through EP_2) blocks 5-LO
►Very little LTA_4 produced
Leukocytes
• Less blockade of 5-LO by PGE_2 (due to less EP_2)
►LTA_4 is produced, passed to adherent platelets
• Platelet-derived TXA_2 downregulates LTC_4S
►Very little LTA_4 converted to cysLTs
Platelets
• Platelet-derived TXA_2 downregulates LTC_4S
►Some LTA_4 converted to cysLTs by adherent platelets
►Low baseline cysLT levels
OUTCOME
►High baseline cysLT levels
Following COX-1 inhibition
• PGE_2 level stays constant through COX-2
► EP_2 signaling keeps 5-LO inactive
► Very little LTA_4 produced
Leukocytes
• PGE_2 production decreases in absence of COX-2
►↓PGE_2 + less EP_2 signaling = 5-LO is activated
►↑LTA_4 is produced
• ↓TXA2 levels
►LTC_4S is upregulated
Platelets
• ↓TXA_2 levels
►LTC_4S is upregulated
• LTA_4 production still low and few adherent platelets to convert it to cysLTs
• LTA_4 converted to cysLTs by eosinophils, mast cells, or adherent platelets
►cysLT levels stay constant
OUTCOME
►cysLT levels rise; respiratory reaction occurs

FIG 48.9 Summary of the pathogenesis of aspirin-exacerbated respiratory disease (AERD) at baseline and after cyclooxygenase 1 (COX-1) inhibition. PGE_2, prostaglandin E2; 5-LO, 5-lipoxygenase; LTA_4, leukotriene A4; LTC_4S, leukotriene C4 synthase; cysLTs, cysteinyl leukotrienes; COX-2, cyclo-oxygenase-2; TXA_2, thromboxane A2; EP_2, prostaglandin E2 receptor 2. (From Laidlaw TM, Boyce JA. Pathogenesis of aspirin-exacerbated respiratory disease and reactions. *Immunol Allergy Clin North Am.* 2013; 33: 195–210.)

with exacerbation of chronic urticaria. Anaphylaxis can occur to a single NSAID with tolerance to all others, but usually there is complete cross-reactivity. Desensitization protocols are available for AERD to ameliorate nasal polyps and increase the sense of smell. Desensitization has also been tried for urticarial reactions.

Biological Agents and Monoclonal Antibodies

The use of mAbs to target cancer and chronic inflammatory diseases has become widespread over the past decade. Inevitably this has led to adverse reactions, which sometimes prevent the use of first-line therapies. Some of the most frequently used mAbs are presented in Table 48.5, including their targets, incidence of overall injection/infusion site reactions, and rates of severe immediate hypersensitivity reactions (HSRs).[51] The immunogenicity of mAbs varies, depending on whether they are chimeric mouse–human, humanized, or fully human mAbs, such as adalimumab and ofatumumab. Reactions to mAbs can occur during the first exposure, as has been reported with cetuximab and trastuzumab or after multiple exposures, such as with rituximab. Infusion-related reactions to mAbs present as cytokine storm-like reactions, with such symptoms as nausea, chills, fever, and malaise. These are thought to be caused by release of proinflammatory cytokines (*e.g.*, IL-1, IL-6, and TNF-α) and respond to NSAIDs and steroids. Hypersensitivity reactions to cetuximab on first exposure have been attributed to sensitization to the galactose-α-1,3-galactose epitope caused by exposure to the lone star tick (*Amblyomma americanum*). The carbohydrate galactose-α-1,3-galactose is expressed on nonprimate mammalian proteins and also on the cetuximab heavy chain.

TABLE 48.5 Biological Agents: Actions, Incidence, and Hypersensitivity Drug Reactions

Drug	Target	Overall Reactions	HSR
Rituximab (Rituxan) IV	CD20	77% (first infusion)	5–10%*
Ofatumumab (Arzerra) IV	CD20	44 % (first infusion) 67% (combination therapy)	2%*
Obinutuzumab (Gazyva) IV	CD20	66%	*
Trastuzumab (Herceptin) IV	HER-2	40% (mild; first infusion)	0.6-5%*
Cetuximab (Erbitux) IV	EGFR	15–21%	1.1–5% 14–27% (Southern USA)*
Tocilizumab (Actemra) IV	IL-6 receptor	7–8%	0.1-0.7%*
Infliximab (Remicade) IV	TNF-α	5- 18%	1%*
Etanercept (Enbrel) SC	TNF-α	15- 37%	<2%*
Adalimumab (Humira) SC	TNF-α	20%	1%*
Golimumab (Simponi) SC	TNF-α	4–20%	Not reported
Certolizumab (Cimzia) SC	TNF-α	0.8–4.5%	Not reported
Brentuximab (Adcetris) IV	CD30	12%	*
Bevacizumab (Avastin) IV	VEGF-A	<3%	*
Omalizumab (Xolair) SC	IgE	45%	00.9–0.2%*

*Case reports of anaphylaxis.

(Modified from Galvão VR, et al. Hypersensitivity to biological agents-updated diagnosis, management, and treatment. *J Allergy Clin Immunol Pract.* 2015 Apr; 3(2): 175–185; quiz 186.)

HSRs to mAbs can also be caused by IgE against antibody moieties, as in some patients sensitized to rituximab. Both immediate and delayed hypersensitivity reactions (skin lesions with CD4 T cells and eosinophilic infiltrates) can occur with tocilizumab.

mAbs given subcutaneously can elicit injection-site reactions, with symptoms including local redness, warmth, burning, stinging, itching, urticaria, pain, and induration. Such reactions can start within 1 hour of the injection and usually resolve over a few days, but large and persistent reactions can lead to discontinuation of the mAb; desensitization protocols have been developed for patients who have no alternative medications (see Table 48.5).

Chemotherapy

Most cancer chemotherapy drugs can induce hypersensitivity reactions. Platins are the agents most able to induce IgE responses. Platin-induced reactions typically occur after several exposures; the incidence of carboplatin allergy is about 27% after seven lifetime exposures and up to 46% in patients who have had 15 or more doses. Patients carrying the *BRCA1* and *BRCA2* mutations are at increased risk for carboplatin hypersensitivity reactions. Most HSRs to platins occur during the infusion, with symptoms consistent with type I reactions, including anaphylaxis (*i.e.*, flushing, hives, wheezing, hypotension). They are generally amenable to desensitization. Positive immediate skin test results to platins have a positive predictive value (PPV) of up to 86% for patients exposed to ≥6 courses of carboplatin, but 50% patients with reactions to oxaliplatin may have negative skin test results, indicating that non-IgE mechanisms may be involved, such as direct activation of mast cells/basophils or a different cell target because some reactions are associated with cytokine storm–like reaction with fever and chills, suggesting IL-6 release. Repeated skin testing before each chemotherapy exposure has been suggested in patients with mild reactions to uncover sensitization before the patient reacts.[52] Adriamycin, cyclophosphamide, methotrexate, topotecan, and other chemotherapies can induce type I reactions, which are also amenable to rapid desensitization.

Taxanes Hypersensitivity

Taxanes include paclitaxel, docetaxel, cabazitaxel, and abraxane. Cremophor is used to solubilize paclitaxel molecules, and polysorbate 80 is used to solubilize docetaxel (Fig. 48.10). These solvents can cause complement activation, leading to generation of anaphylatoxins and mast cell activation. Initially, the side effects of paclitaxel were attributed to cremophor; these responded to premedication with antihistamines and high-dose corticosteroids. Despite using premedication, HSRs occur in up to 10% of patients treated with paclitaxel, and in 1% the reactions can be severe, necessitating discontinuation of the medication. Reactions

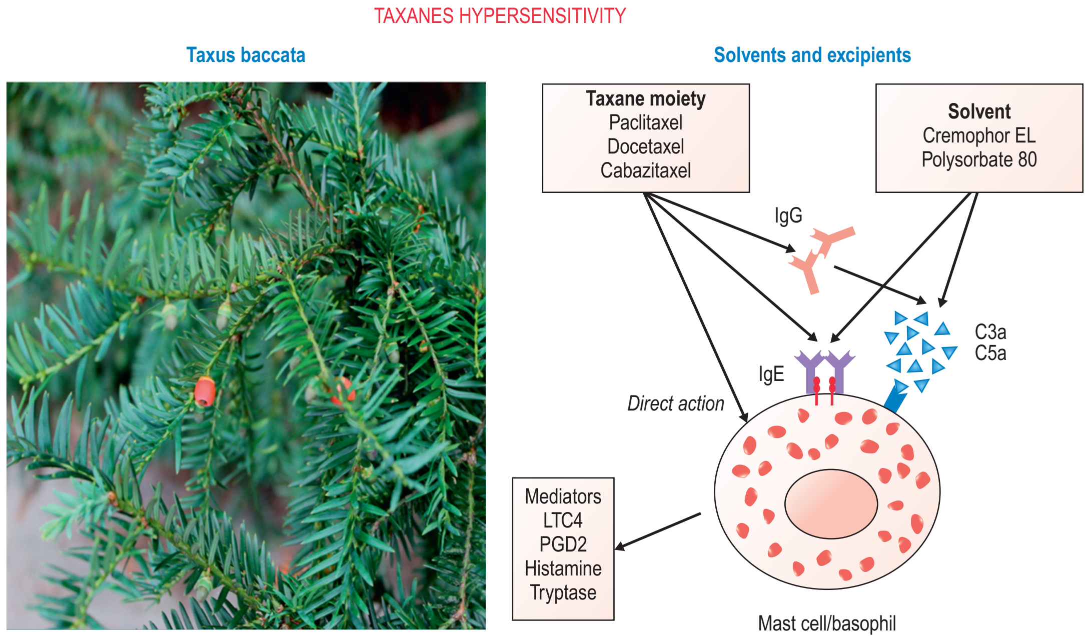


FIG 48.10 Taxanes: Plant origin, solvents, and excipients.

typically occur during the first or second lifetime exposure with such symptoms as throat tightness, flushing, hypotension, and dyspnea. However, some patients also report severe chest, back, and/or pelvic pain.

IgE-mediated HSRs to taxane molecules have been reported, leading to skin test evaluations for patients with taxane reactions. When skin testing was performed in 145 patients with taxane-related HSRs, 103 (71%) had positive results. Thirty-six (22%) patients with negative skin test results eventually resumed regular infusions.[53]

MANAGEMENT OF DRUG HYPERSENSITIVITY AND DESENSITIZATION

Stopping a drug suspected of inducing a reaction has therapeutic and diagnostic implications. If the symptoms are alleviated upon cessation, it is likely, but not certain, that the drug was responsible for the reaction. Although most type I symptoms are readily reversible, death has occurred in patients on concomitant beta-blockers or ACE inhibitors when epinephrine did not reverse cardiovascular collapse. Patients with severe anaphylactic drug reactions, as seen with chemotherapy and platins, may develop posttraumatic stress disorders. Severe reactions, such as DRESS, SJS, and TEN, do not have specific therapies and require intensive and aggressive treatments, including steroids and/or immunoglobulin infusion at high doses, to accelerate the resolution of inflammatory events and facilitate recovery. Recurrence of these reactions upon inadvertent exposure can be lethal, and those surviving can suffer life-debilitating consequences, such as depression and increased suicides. Blindness, permanent hair and nail loss, mucosal dryness, and fibrosis can dramatically decrease the quality of life in patients with SJS and TEN, and patients with DRESS can have persistent hepatitis and/or eosinophilic cardiac complications.

For type I IgE- and non–IgE-mediated reactions, desensitization is now the state-of-the-art management option in patients who still require the offending drug as first-line therapy. Desensitization has been successfully achieved for chemotherapy drugs, mAbs, antibiotics, and other medications in both adults and children. Although drug reactions are less common in children than in adults, perhaps because of fewer exposures, patients with cystic fibrosis have an average 30% sensitization rate to antibiotics; they can be successfully desensitized with first-line antibiotics, even during lung transplantation. The mechanism of desensitization for IgE-mediated reactions has been studied *in vitro* and in rodents. Although antigen induces membrane changes leading to internalization of the antigen, IgE and FcεRI, when cells are repeatedly exposed to increasing suboptimal drug concentrations, this prevents these membrane events and blocks calcium entry and the release of inflammatory mediators (Fig. 48.11). Other mechanisms that may be relevant to human desensitization have also been implicated (Fig. 48.12). Further research is needed to better understand these.

Application of the principles of desensitization has been remarkably successful, and thousands of patients have been safely desensitized, including patients suffering severe anaphylactic reactions. Indications for desensitization include type I IgE- and non–IgE-mediated reactions. The risk/benefit ratio needs careful consideration because desensitization can sometimes induce severe reactions. If there is a good alternative drug, desensitization should not be attempted. Desensitization protocols generally involve diluting the drug up to 1/1000 of its normal concentration, followed by doubling doses at short intervals. A 12-step protocol for carboplatin desensitization is shown in Table 48.6. For patients with high risk, four bags and 16 steps may be used as shown in Table 48.7 for ofatumumab. For patients with local and systemic reactions to subcutaneous injections, desensitization has been successfully achieved by the subcutaneous route.

ON THE HORIZON

- There is a need for a new mechanistic approach and categorization of delayed hypersensitivity reactions, better diagnostic tools, and a standardized approach to desensitization protocols.
- Modulation and treatment of hypersensitivity reactions will include the use of anti–IgE and other mAbs as well as small molecules to inhibit signal transduction.
- Prevention of hypersensitivity reactions will include the identification of patients at risk by HLA genotyping.
- Drug desensitization should be more widely available. Patients with allergies can then be treated with first-line therapies, which will improve quality of life and reduce both costs and risks.

MULTIPLE-CHOICE QUESTIONS

1. Human herpesvirus 6/7 reactivation during an adverse drug reaction is frequently seen in:
   A. Stevens Johnson syndrome
   B. Toxic epidermal necrolysis
   C. Maculopapular exanthema
   D. Drug reaction with eosinophilia and systemic symptoms

2. Screening for which human leukocyte antigen (HLA) alleles should be done in a patients with carbamazepine-induced Stevens-Johnson syndrome/toxic epidermal necrosis (SJS/TEN)?
   A. HLA-B* 57:01
   B. HLA-B* 15:02
   C. HLA-B* 13:01
   D. HLA-B* 58:01

3. The *most* important risk factor associated with allergic reactions to carboplatin in women with ovarian cancer include:
   A. High cancer burden with metastatic disease
   B. *BRCA1* and *BRCA2* mutations
   C. Food allergy
   D. Asthma

4. Patients with sulfonamide antibiotic allergy:
   A. Typically present with IgE-mediated reactions
   B. Can use nonantibiotic sulfonamides
   C. Are not at risk for reactions to other antibiotics
   D. Cannot be desensitized

5. Drug desensitizations:
   A. Are limited to type I, IgE-mediated reactions
   B. Are not performed in patients with anaphylaxis
   C. Can induce drug tolerance
   D. Require specific protocols based on the dose, initial reaction, and patient risk

6. Serum markers of drug hypersensitivity and mast cell activation include:
   A. Histamine
   B. Complement CH50
   C. Tryptase
   D. Bradykinins

Occupational Respiratory Allergies

Catherine Lemière, James G. Martin

Occupational asthma (OA) is a unique phenotype of asthma, which provides us with an opportunity to understand the origins not only of OA but also of asthma in general. In the vast majority of cases, the onset of OA occurs in adulthood, in response to a specific exposure at work. As such, it opens a unique window on the natural history of asthma and the risk factors associated with the risk of development of the disease. This chapter will review the mechanisms of occupational sensitization, the evaluation of the disease from exposure to the manifestation of the disease clinically, and the main steps in diagnosis and management of sensitizer-induced OA.

KEY CONCEPTS

- Occupational sensitizers induce sensitization through different mechanisms, depending on their nature (proteins vs chemicals).
- Atopy, rhinitis, and genetic markers are host risk factors predisposing to develop occupational asthma (OA).
- The level of exposure to the causal agent is the main environmental risk factor predisposing to development of OA.
- Experimental models support roles for a diverse range of lymphocytes in airway hyperresponsiveness (AHR) and inflammation induced by allergens and nonallergenic stimuli.
- Objective confirmation of a diagnosis of OA is crucial because of socioeconomic implications for affected workers.

MECHANISMS OF OCCUPATIONAL SENSITIZATION

More than 400 distinct agents have been documented as causing OA.[1] The type of agents to which the subjects are exposed drives different pathophysiological mechanisms. The agents responsible for OA are usually considered according to their molecular weights. High-molecular-weight (HMW) agents (>10 kilodaltons [kDa]) include proteins of animal and vegetable origin and microorganisms, whereas low-molecular-weight (LMW) agents include wood dust, drugs, metals, and chemicals. Exposure to HMW agents usually induces the production of allergen-specific immunoglobulin E (IgE), whereas only a few LMW agents have been associated with the production of specific IgE.[2]

IgE-Mediated

HMW agents are proteins and in general bear similarities to the aeroallergens triggering usual allergic asthma. They act as complete antigens provoking the production of specific IgE antibodies. Sensitization involves the uptake of antigen by immature dendritic cells (DCs) residing in the subepithelial space within the airway walls.[3] DCs extend cellular projections between the epithelial cells and are believed to sample the airway microenvironment. Once antigen has been taken up, the DC migrates to regional lymph nodes, undergoes maturation, and expresses antigenic peptide on its surface in conjunction with major histocompatibility complex (MHC) type II molecules. In this location, they encounter circulating CD4 T lymphocytes that stochastically sample the DC surface.[4] The DC eventually interacts with CD4 T cells expressing high affinity receptors for the antigen–MHC II complex. The T cells expand and exit the lymph node, and T-helper-2 (Th2) cells will eventually resettle in the airways, attracted by chemokine gradients, in particular, the macrophage-derived chemokine (MDC) CCL22 and the thymus and activation-regulated chemokine (TARC) CCL17, which are secreted by epithelial cells and act on their cognate receptor CCR4 on the T cells. In the airways, CD4 T cells may react to antigen presentation locally on future exposures,[5] synthesizing interleukin (IL)-4, IL-5, and IL-13. Certain characteristics of antigens, such as protease activity or endogenous nicotinamide adenine dinucleotide phosphate (NADPH) oxidase activity, have been associated with allergenicity, likely through the effects of these stimuli on epithelial cells, which, in turn, secrete cytokines that not only favor the development of Th2 cells but also activate novel innate lymphoid cells that themselves produce type 2 cytokines. Th2 cells provide key help to B cells to undergo isotype switching and produce IgE. The binding of IgE to both high- and low-affinity receptors on a number of cells and its subsequent interaction with antigen not only result in mediator release from mast cells and basophils but also have effects on the functions of other cells, such as neutrophils and smooth muscle cells.[6]

A few LMW occupational agents also induce specific IgE antibodies, but they do so by acting as haptens and binding with proteins to form functional antigens. Specific IgE to isocyanates and plicatic acid (western red cedar, *Thuja plicata*) have been identified. However, the significance of finding specific IgE to isocyanates or plicatic acid is not so straightforward to interpret. In contrast, OA caused by platinum salts or acid anhydrides is clearly IgE mediated, and so the presence of specific IgE to those agents is a useful additional tool for making a diagnosis of OA to those agents.

Non–IgE-Mediated

Cell-mediated reactions are likely to play an important role in OA because of LMW agents. Although the predominant immune response to chemical respiratory allergens may be of the Th2 type, other cells may play important support or regulatory roles. CD4 as well as CD8 T cells and different cytokines, such as IL-1, IL-4, IL-5, IL-6, and IL-15, have been found in the biopsy material, bronchoalveolar lavage (BAL), and sputum of patients with

TABLE 49.1 Summary of the Most Frequently Encountered Occupational Agents Causing Occupational Asthma (OA)

Agents	Occupation/Industry
High-Molecular-Weight Agents	
Immunoglobulin E (IgE)–Dependent Causes	
Cereals, flour	Flour mills, bakers, pastry makers
Animal-derived allergens: laboratory animals	Laboratory workers, farmers
Enzymes: α-amylase, maxatase, alcalase, papain, bromelain, pancreatin	Baking product production, bakers, detergent production, pharmaceutical industry, food industry
Seafood	Seafood processing
Latex	Health care workers, laboratory technicians
Low-Molecular-Weight Agents	
IgE-Dependent Causes	
Acid anhydrides, phthalic, trimellitic, tetrachlorophthalic anhydrides	Epoxy resin workers
Platinum salts	Platinum refining
Other Potential Immunological Mechanisms	
Diisocyanates: toluene diisocyanate (TDI), methylene diphenyl-diisocyanate (MDI), hexamethylene diisocyanate (HDI)	Polyurethane production, plastic industry, insulation, molding, spray painting
Wood dusts: western red cedar, iroko, obeche, oak, and others	Sawmill workers, carpenters, cabinet and furniture makers
Amines and epoxy resins	Rubber industry, cosmetics, hair dye manufacturing, fur industry, rubber additives
Colophony	Electronic industry (flux)
Acrylates: cyanoacrylates, methacrylates, di- and triacrylates	Adhesives, dental and orthopedic materials, sculptured fingernails, printing inks, paints and coatings
Pharmaceutical products	Pharmaceutical industry
Formaldehyde, glutaraldehyde, biocides	Health care workers, cleaners
Persulfate salts: hair bleach	Hairdressers
Reactive dyes: reactive black 5, pyrazolone derivatives, vinyl sulfones, carmine	Textile workers, food industry workers
Metals: chromium, nickel, cobalt	Metal refinery, metal alloy production, electroplating, welding

isocyanate-induced asthma. Murine models of toluene diisocyanate "asthma" have shown a dependence of airway hyperresponsiveness (AHR) and Th2-type inflammation on both CD4 and CD8 cells, but primarily the former. IL-4 and IL-13 are major determinants of the pathobiology. Recent studies have suggested a role for innate lymphoid (lineage negative) cells to contribute to type 2 cytokine production in the airways in response to nonallergenic stimuli. Although few in number, these type 2 innate lymphoid cells can produce significant quantities of IL-5 and IL-13. IL-13 is a pleiotropic cytokine affecting the epithelium, smooth muscle, and immune cells and possibly drives asthma that is induced by allergens or irritants. The potent oxidant ozone induces AHR in the mouse through activation of inducible natural killer (NK) cells, so similar mechanisms may apply in human subjects exposed to molecules that cause oxidative stress.

Neutrophils are also likely to be involved in isocyanate-induced asthma, as shown by an increase in myeloperoxidase and IL-8 after exposure to toluene diisocyanate (TDI). A mixed Th1/Th2 pattern of cytokine production has been observed in subjects with red cedar–induced asthma. Furthermore, a specific inhalational challenge test induced a mixed Th1/Th2 response in which CD8 T cells were the main producers of interferon (IFN)-γ. However, histopathological changes in the airways in isocyanate-induced asthma are similar to those found in atopic asthma that is not associated with occupational sensitization.

There is evidence that isocyanates can stimulate human innate immune responses by upregulating immune pattern recognition receptors on monocytes and increasing the chemokines that regulate monocyte/macrophage trafficking (macrophage migration inhibitory factor [MIF], monocyte chemoattractant protein-1 [MCP-1]). Furthermore, repetitive antigenic stimulation of peripheral blood mononuclear cells from patients with diisocyanate asthma induced the synthesis of tumor necrosis factor (TNF)-α and MCP-1, but not IL-4 or IL-5. The bioactive lipid lysophosphatidic acid is released from lung epithelial cells by allergen or isocyanate and has the potential to contribute to the pathogenesis of asthma through a number of biological effects.

Table 49.1 summarizes the most frequent agents responsible for occupational asthma.

NATURAL HISTORY OF OCCUPATIONAL ASTHMA AND RISK FACTORS

Natural History of the Development of the Disease

Studies performed in apprentices shed light on the natural history of occupational asthma and risk factors for developing occupational asthma. Epidemiological studies give some indication of the course of the disease. Atopy and exposure levels have been shown to predict sensitization to laboratory animals; sensitization has been shown to precede the occurrence of rhinitis and asthma at the workplace.[7]

Risk Factors

The occurrence of OA is the result of an interaction between environmental and host factors (Fig. 49.1). Several host factors have been shown to increase the risk of developing OA (Table 49.2).

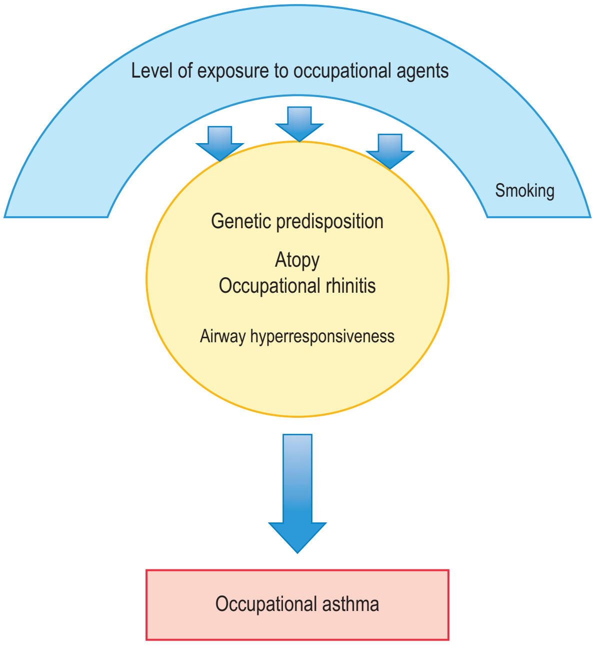

FIG 49.1 Environmental and host factor favoring the occurrence of occupational asthma.

TABLE 49.2 Risk Factors Associated With the Occurrence of Occupational Asthma (OA)

Risk Factor	Mechanisms
Environmental Factors	
High level of exposure Cigarette smoking	Activation of airway epithelium and sensory nerves through Toll-like receptors (TLRs) and transient receptor potential (TRP) channels.
Host-Related Factors	
Atopy	Promotion of a T-helper-2 (Th2) phenotype by multiple environmental stimuli when interacting with dendritic cells (DCs), including interleukin-4 (IL-4), thymic stromal lymphopoietin (TSLP), eosinophil-derived neurotoxin (EDN), and cysteinyl leukotrienes. Facilitation of antigen presentation by immunoglobulin E (IgE) binding to B cells and DCs
Genetic markers	The genetic polymorphisms identified do not yet lead to clear explanations of the known pathophysiological processes.
Preexisting nonspecific bronchial hyperresponsiveness and work-related rhinitis	Airway remodeling may be necessary before asthma becomes manifest in subjects with rhinitis.

Host Factors

Atopy

Clinical evidence. Atopy is clearly associated with increased risk of sensitization to HMW agents. For example, atopy has been identified as one of the determinants for sensitization to rodents in apprentices working in animal facilities.[7] Furthermore, the vast majority of apprentices who become sensitized to HMW agents have atopy, in contrast to those who do not get sensitized.[7] Therefore, and not surprisingly, atopy is also a risk factor for developing OA to HMW agents, since subjects who develop OA need to be sensitized to a specific agent to develop an asthmatic reaction on exposure. Atopy has been associated with OA to several different HMW agents, including OA caused by flour, laboratory animals, latex, snow crab, detergent enzymes, and α-amylase. It seems that the sensitization to specific allergen occurs mainly in the first 1–2 years after the beginning of exposure.[8] However, atopy does not seem to influence the timing of onset of OA symptoms.[9]

Pathophysiology. The predisposition to atopy has increased markedly in recent years. The explanation for the increase is considered to be largely environmental but has not been fully identified, although airborne particulates have been shown to have adjuvant effects and may, therefore, play a part. The hygiene hypothesis has led to evidence of protective effects of certain environments, such as the farm. A fundamental question remains as to why T-cell differentiation into Th2 cells occurs in the airways. Multiple stimuli within the airway environment have been shown to promote a Th2 phenotype when interacting with DCs, including IL-4, thymic stromal lymphopoietin (TSLP), eosinophil-derived neurotoxin, and cysteinyl leukotrienes. Interaction of antigens directly with airway epithelial cells releases alarmins, such as IL-33, and TSLP, which condition DCs such that their interactions with CD4 T cells direct them to produce Th2 type cytokines. These epithelial-derived cytokines also direct innate lymphoid cells to produce type II cytokines.

Certain characteristics of antigens, such as protease activity or endogenous NADPH oxidase activity, have been associated with allergenicity.[10,11] Binding of IgE to B cells and DCs facilitates the process of antigen presentation and provides a potential explanation for the predisposition, once sensitization to one allergen has occurred, to develop allergy to unrelated antigens.[6]

Rhinitis and airway hyperresponsiveness

Clinical evidence. The presence of AHR and rhinitis before entering a workplace is an independent risk factor for subsequent IgE sensitization to allergens present at the workplace. The development of occupational rhinitis during exposure often precedes the occurrence of OA. However, the predictive value of work-related nasal symptoms is only 11.4% for the subsequent development of OA in workers exposed to laboratory animals, over a follow-up period of 30–42 months.[2]

Pathophysiology. The onset of allergic rhinitis before asthma suggests that additional pathophysiological factors are required for the expression of lower airway disease. The inflammation affecting the upper airway is generally felt to be representative of that present concurrently in the lower airway. However, the clinical expression of lower airway disease requires that the airways become reactive to the mediators of bronchoconstriction and mucus secretion, such as cysteinyl leukotrienes. The mechanism(s) of the increase in airway responsiveness remains uncertain but may involve growth of airway smooth muscle and/or changes in airway smooth muscle contractility through increase in expression of smooth muscle proteins. Other possible contributory changes include altered matrix deposition, an increase in mucous glands, and goblet cell hyperplasia, all of which are forms of airway remodeling that may be required before asthma becomes clinically manifest.

Genetic predisposition

Clinical evidence. There has been a tremendous effort to identify genetic predisposition for subjects developing occupational asthma. Certain human leukocyte antigen (HLA) class II molecules (*i.e.*, HLA-DR, HLA-DQ, and HLA-DP alleles) were found to be factors that either placed subjects at risk of OA or were protective against OA caused by various LMW and HMW agents. Genes associated with Th2-cell differentiation may also play a role in the development of OA. Increased risks of developing isocyanate-induced asthma may be associated with genetic variations in transforming growth factor (TNF)-α, TGF-β1, PTGS1(cyclooxygenase-1), and PTGS2 (cyclooxygenase-2) genes, as well as genes involved in the protection against oxidative stress, such as glutathione-S-transferase and N-acetyltransferase. Genome-wide association studies have identified genetic polymorphisms in catenin α-3, α-T catenin (CTNNA3) associated with isocyanate-induced asthma. Although some genetic markers seem to indicate susceptibility or a protective effect for developing OA, we are not yet ready to use these in clinical practice.[12]

Pathophysiology. As is frequently the case, the genetic polymorphisms identified do not lead to clear explanations of the known pathophysiological processes but often appear to be peripheral to the issue of excessive airway narrowing. Although genes associated with inflammatory processes and oxidative stress are expressed in association with OA driven by HMW or LMW agents, the precise mechanistic links await elucidation. Catenins are linked to epithelial cell adhesion processes and differentiation and, as such, may affect epithelial responses to injury or inflammation. Allergens that trigger neutrophilic inflammation will necessarily cause oxidative stress, as neutrophils are a rich source of reactive oxygen species and produce hypochlorite in high concentrations within the airway lumen. Prostaglandin synthesis may also result in proinflammatory effects, vasodilation, and airway smooth muscle constriction.

Environmental Factors

Level of exposure. The level of exposure to sensitizers has been well established as a strong predictor of the occurrence of OA and appears as the most important environmental risk factor for developing OA. A dose–response relationship has been identified between the level of exposure to HMW agents and the occurrence of IgE-mediated sensitization and OA. Such a dose–response relationship has also been documented for some LMW agents, such as platinum salts, acid anhydrides, and isocyanates.[2]

Tobacco smoke and irritants. Cigarette smoking may increase the risk of IgE-mediated sensitization to some HMW and LMW agents, although the association between smoking and the occurrence of OA is weak. The role of other environmental cofactors, such as nonrespiratory routes of exposure and concomitant exposure to endotoxin and pollutants at work, remains largely uncertain. Exposure to pollutants augments the response to allergens.[13] It is also possible that exposure to irritants in the workplace modifies the immunological response to sensitizers.

Pathophysiology. Exposures in the workplace may be complex and do not only involve sensitizing substances. It is increasingly recognized that nonimmunological stimuli, such as endotoxin, cold, and irritants, activate the airway epithelium and sensory nerves through Toll-like receptors (TLRs) and transient receptor potential (TRP) channels. The release of proinflammatory mediators may be predicted to evoke neutrophilic inflammation directly but also favors eosinophilic inflammation by the release of mediators favoring Th2-cell differentiation or type II innate lymphoid cell stimulation. Experimental models have shown a dependence of allergic sensitization on concomitant TLR4 activation by endotoxin, although in high concentrations Th2-cell inflammation is inhibited. In addition, TRPA1 is activated by stimuli, such as cigarette smoke, chlorine, aldehydes, scents, and endogenous products of oxidative stress, and has been shown to be essential for allergic "asthma" in a murine model.[14] Confirmation of such mechanisms in humans is required.

DIAGNOSIS AND MANAGEMENT OF OCCUPATIONAL ASTHMA

Diagnosis of Occupational Asthma

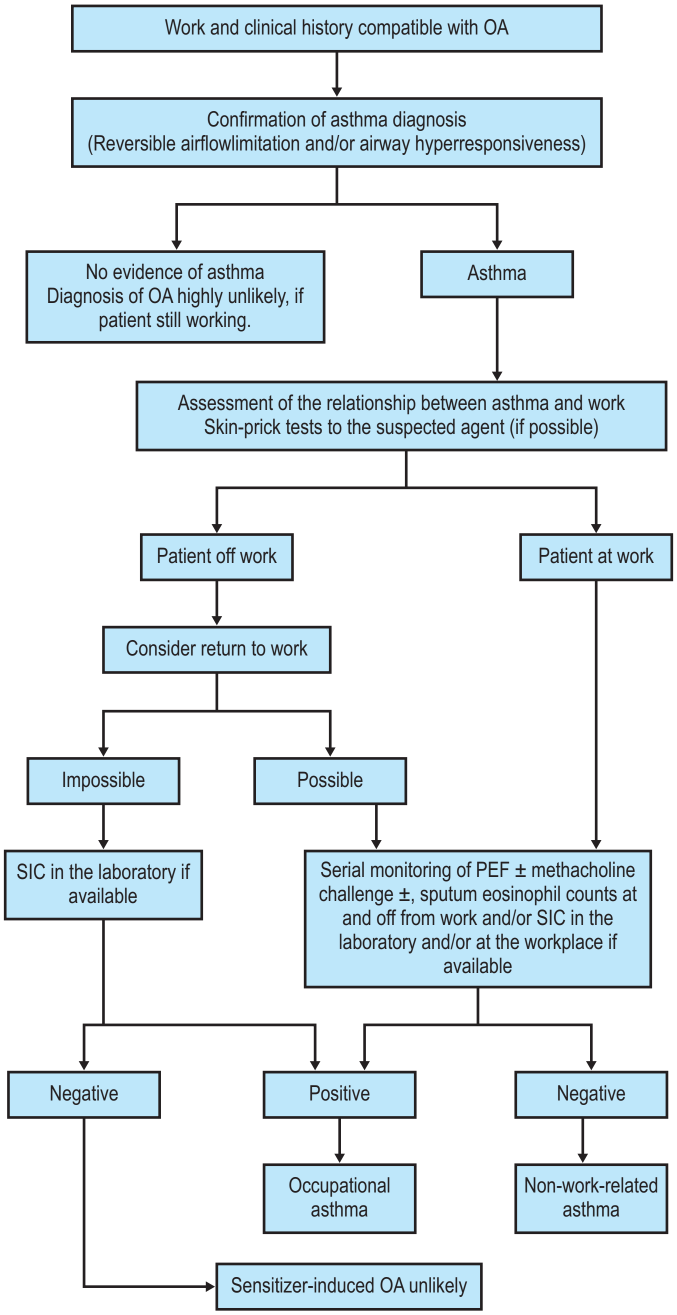
Sensitizer-induced OA should be suspected in every worker exposed to potential sensitizers with new-onset asthma or with asthma that has become difficult to control. The diagnosis of OA should not be discarded only on the basis of the time between onset of asthma and the beginning of the occupational exposure, since approximately 20% of subjects with OA report having childhood asthma or asthma onset before entering the workforce. Although some of them had a remission of their asthma before entering the workforce, many of them still experience asthma symptoms when entering the workforce.[15,16]

The respiratory symptoms (*e.g.*, dyspnea, chest tightness, wheezing, cough, and sputum production) are similar to those encountered in non–work-related asthma, but in OA, their occurrence is usually modulated by the work exposure. The symptoms can start at the beginning of the work shift, toward its end, or even after working hours, with remission or improvement during weekends and holidays. Rhinitis often precedes the occurrence of the respiratory symptoms, especially with HMW agents. A thorough clinical and occupational history must be carefully recorded, but the diagnosis of OA cannot be made only on the basis of a compatible history, which has a low positive predictive value. A comprehensive investigation should be performed to accurately diagnose OA.[1] Fig. 49.2 summarizes the different steps leading to a diagnosis of OA.

The investigation of OA should start as soon as the diagnosis is suspected, as a long duration of exposure after the occurrence of respiratory symptoms is associated with a poor prognosis. Immunological assessment is particularly important for the diagnosis of HMW agents. Skin prick tests or serological assessment of specific IgE have a high sensitivity but a relatively poor specificity, since they indicate sensitization, which is necessary but not sufficient for the disease. Unfortunately, immunological tests are limited by the lack of standardized commercially available reagents for skin and *in vitro* tests for allergens implicated in OA.

In any case, the diagnosis of asthma needs to be confirmed in a worker who has a clinical and occupational history compatible with OA, by documenting reversible airflow limitation and/or AHR.[17] Although the lack of AHR does not exclude the diagnosis of OA in subjects who have been removed from exposure, in subjects that are still working a negative methacholine challenge has a 95% negative predictive value for excluding the diagnosis of OA.[18] The work-relatedness of asthma should be assessed through serial measurements of peak expiratory flow (PEF) and/or AHR at work and off work and/or specific inhalation challenges in the laboratory or at the workplace.

Specific inhalation challenge tests involve exposing the subject to the putative cause of OA in the laboratory and/or at the workplace.[19] Although these tests are considered reference tests for diagnosing OA, they are only available in a small number of



Work and clinical history compatible with OA
Confirmation of asthma diagnosis (Reversible airflowlimitation and/or airway hyperresponsiveness)
No evidence of asthma Diagnosis of OA highly unlikely, if patient still working.
Asthma
Assessment of the relationship between asthma and work Skin-prick tests to the suspected agent (if possible)

Non-work-related asthma
Sensitizer-induced OA unlikely

FIG 49.2 Stepwise approach for diagnosing occupational asthma.

centers worldwide. Specific challenge tests are especially useful when *(i)* the diagnosis of OA remains uncertain after measurement of serial PEF or monitoring of airway responsiveness; *(ii)* a patient clearly has OA, but the causal agent needs to be identified; *(iii)* a new agent is suspected of causing OA; and *(iv)* the patient cannot be returned to the incriminated workplace. A false-negative response can occur if the wrong agent is used or if the exposure conditions are not comparable with those in the workplace.

Eosinophilic inflammation has been shown to increase after exposure to the causal agent(s) in the majority of subjects with OA. An increase in sputum cell count >3% after exposure to the suspected occupational agent has a specificity of 97% for a diagnosis of OA.[20] Although fractional concentration of expired nitric oxide (FeNO) levels are correlated with eosinophilic airway inflammation, the sensitivity of FeNO measured 24 hours after exposure appears to be too low (37%) to be useful in clinical practice.[21]

MANAGEMENT OF OCCUPATIONAL ASTHMA

Workers with sensitizer-induced OA who continue to be exposed to their causal agent are at a high risk of deterioration of asthma symptoms, airway obstruction, and nonspecific AHR. Complete and definitive avoidance of exposure to the causal agent is the optimal treatment for immunological OA. However, complete elimination of exposure or reassignment of affected workers to jobs that avoid exposure is not always possible. Reduction of exposure to the agent causing OA has been assessed as an alternative option to total avoidance. Unfortunately, this option is associated with a lower likelihood of asthma improvement and a higher risk of worsening. Therefore this management approach should be restricted to selected patients and requires careful medical monitoring to ensure early identification of asthma worsening.

Small uncontrolled studies suggest that immunotherapy may be effective in some cases of OA caused by HMW agents. However, some safety concerns remain. Further studies need to be conducted before immunotherapy can be recommended for OA to HMW agents.

Anti-IgE (omalizumab) may improve asthma control in subjects with flour-induced OA who remain exposed to the work environment, although further prospective investigations are required in subjects who choose to remain in an environment of exposure.

Even in spite of complete removal from exposure to the offending agent, asthma symptoms and AHR to methacholine persist in approximately 70% of the patients with OA several years after removal from the offending environment. Besides environmental interventions, pharmacological treatment of OA should follow standard clinical practice guidelines for asthma.

ON THE HORIZON

- Identification of new genetic markers may allow the identification of subgroups with high or low risks of developing occupational asthma (OA).
- Identification of new biomarkers may improve the diagnosis of OA.
- Identification of different OA phenotypes and endotypes that may improve the management of the disease.

Our understanding of how and why OA develops in a given individual has improved within the last 20 years, but many aspects remain obscure. Awareness that the level of exposure plays a pivotal role in the occurrence of sensitization has helped improve primary prevention of the disease. Although several markers of genetic predisposition have been identified, these findings have not yet been translated into biomarkers that can be used in clinical practice. Once OA is present, there is no reliable and effective medication to cure it. Instead, a thorough and timely investigation needs to be performed to diagnose it with certainty and then remove the patient from exposure to ensure the best possible prognosis.

MULTIPLE-CHOICE QUESTIONS

1. Which characteristics have been identified as risk factors for developing occupational asthma (OA)?
   A. Atopy
   B. Obesity
   C. Smoking
   D. Genetic markers
   E. None of the above

2. In a subject with a history of childhood asthma who decided to quit his work because of recurrence of asthma, which factors can exclude the diagnosis of occupational asthma (OA)?
   A. Childhood asthma
   B. Absence of airway hyperresponsiveness (AHR)
   C. Normal spirometry
   D. Absence of eosinophilic inflammation
   E. None of the above

3. In a subject with diagnosed sensitizer-induced occupational asthma (OA) what is the most effective intervention?
   A. Complete removal from exposure
   B. Reduction of exposure
   C. Treatment with anti–immunoglobulin E (IgE) therapy
   D. Immunotherapy to the occupational agent.

Mechanisms of Autoimmunity

Brendan Antiochos, Antony Rosen

Human autoimmune diseases occur frequently (affecting in aggregate >5% of the population worldwide) and impose a significant burden of morbidity and mortality on the human population.[1] Autoimmune diseases are defined as diseases in which immune responses to specific self antigens contribute to the ongoing tissue damage occurring in the disease. Both the specificity of the immune response and its role in tissue damage are central components of the definition. Autoimmune diseases can be either tissue specific (*e.g.*, thyroid, β-cells of the pancreas), where unique tissue-specific antigens are targeted, or can be more systemic, in which multiple tissues are affected and a variety of apparently ubiquitously expressed autoantigens are targeted.[2] Although the definition appears relatively simple in concept, the complexity of this spectrum of disorders is enormous and has greatly challenged elucidation of simple shared mechanisms. This complexity affects almost every domain, including genetics, phenotypic expression, and kinetics. In the last case, there is frequently a prolonged period (weeks to months) between initial onset of symptoms and development of the diagnostic phenotype, and the expression of disease may vary within the same individual over time. However, despite this enormous complexity, there is a striking association of the clinical phenotype with the targets of the autoimmune response. This association is, in fact, so strong that autoantibodies have been used for diagnosis and prognosis in the human autoimmune diseases.[2] For example, autoantibodies recognizing thyroid peroxidase are found in patients with autoimmune thyroiditis, autoantibodies to the Sm splicing ribonucleoprotein (RNP) complex are diagnostic of systemic lupus erythematosus (SLE), and autoantibodies recognizing topoisomerase-1 are found in patients with the diffuse form of scleroderma. The immune response in autoimmune diseases has features of an adaptive immune response (usually directed against exogenous antigens), but its targets are autoantigens. Since the adaptive immune response is initiated when suprathreshold concentrations of molecules with structures not previously tolerized by the host are encountered in a proimmune context, the association of specific autoantibodies with distinct clinical phenotypes provides critical clues to understanding the initiation and propagation of autoimmune diseases.

This chapter highlights some of the mechanistic principles that underlie autoimmune diseases. The extraordinary breadth and complexity of this disease spectrum means that the areas included cannot nearly encompass everything relevant.

KEY CONCEPTS

Autoantibodies in Autoimmune Diseases

- Some autoantibodies precede the development of any symptoms by years (*e.g.*, antinuclear antibodies and antiphospholipid antibodies in systemic lupus erythematosus [SLE], anti– cyclic citrullinated peptide [CCP] in rheumatoid arthritis [RA]).
- Some autoantibodies only occur at around the time of onset of disease manifestations (*e.g.*, anti-Sm and anti-ribonucleic protein [RNP] in SLE).
- There is a striking association of specific autoantibodies with distinct clinical phenotypes (*e.g.*, antitopoisomerase-1 with diffuse scleroderma and interstitial lung disease).

THE DISTINCT PHASES IN THE DEVELOPMENT OF AUTOIMMUNITY

A major barrier to understanding mechanisms of autoimmunity comes from difficulty in defining early events in these diseases. Since diseases are only recognizable after development of the diagnostic phenotype, there has been a tendency to interpret findings at the time of disease diagnosis with events present at disease initiation. Significant recent data from studies of the development of autoantibodies over time in patients who subsequently manifest an autoimmune disease have demonstrated that the onset of an autoimmune response and the development of clinical symptoms are generally separated in time. In the case of type I diabetes, development of islet cell autoantibodies frequently precedes diabetes, and additional islet cell autoantibodies accrue over time.[3] Similarly, autoantibodies recognizing citrullinated proteins (rheumatoid arthritis [RA]–specific autoantibodies; see below) frequently precede the development of RA.[4] These findings indicate that either a threshold needs to be exceeded in terms of tissue damage before symptoms manifest, or that there are two distinct phases in disease development, one marked by production of a group of autoantibodies and the second by autoamplifying tissue damage. In a landmark study in SLE, Arbuckle et al. have provided important insights into this issue.[5] They analyzed sera collected from patients from the US military, who subsequently developed SLE. Strikingly, autoantibodies in SLE could be divided into two groups: *(i)* those that precede the diagnosis of SLE by several years—these included antinuclear and antiphospholipid antibodies; and *(ii)* those that occurred around the time of onset of symptoms—these included anti-Sm, anti-RNP, and to a lesser extent anti-DNA. The observation that one group of autoantibodies precedes symptoms in SLE and that another group appears coincident with the phenotype strongly suggests that the groups mark distinct events in the development of autoimmune disease. Members of the first group are likely markers of disease initiation; members of the second group are likely markers of disease propagation. The antigens targeted by the immune system in this latter phase (*i.e.,* associated with clinical disease) are more likely to have some function in disease propagation, possibly through their possession of proinflammatory or adjuvant functions (see below).[6]

KEY CONCEPTS

Barriers to Defining Mechanisms of Human Autoimmune Disease

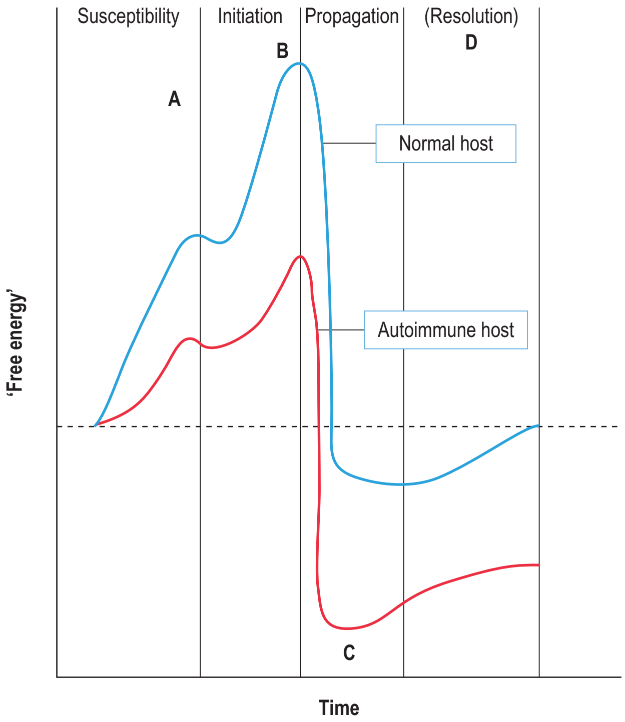
- Genetic and phenotypic complexity
- Interval between initiating events and development of diagnostic phenotype
- Challenges in quantifying human immune responses

It is therefore useful to examine the development of autoimmune diseases in four phases (Fig. 50.1):

1. *Susceptibility phase*—before disease, but where one or several preconditions for later initiation are satisfied. This would include impaired tolerance induction or altered immune signaling thresholds. The susceptibility phase could either be inherited or acquired and permanent or transient.
2. *Initiation phase*—before onset of clinical disease, but marked by the presence of an autoimmune response (*e.g.,* in the case of SLE—antiphospholipid antibodies).
3. *Propagation phase*—this corresponds with the onset of clinical disease, marked by propagation-specific immune responses (*e.g.,* in the case of SLE—anti-Sm antibodies).
4. *Regulation/resolution phase*—it should also be noted that in many cases during disease propagation, immunoregulatory pathways are also activated, which may result in natural inhibition of clinical disease over time. In rare cases, these inhibitory pathways can lead to permanent resolution. This resolution phase will not be discussed further here, but its existence provides important evidence that homeostasis can be reestablished even after the amplified phenotype develops.

PHASE I: SUSCEPTIBILITY

Although autoimmune diseases in humans are genetically complex, significant advances in understanding have occurred over the past several years. In some cases, advances have come from the study of autoimmunity with mendelian patterns of inheritance (*e.g.,* autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia [APECED], immune dysfunction/polyendocrinopathy/enteropathy/X-linked [IPEX] syndrome, C1q deficiency). Advances have also come from genetic association studies of various autoimmune phenotypes (*e.g.,* SLE, type I diabetes mellitus [DM]). There have also been important advances in the genetics of autoimmunity in several mouse models. These studies highlight a critical role for pathways of tolerance induction, immunoregulation, and setpoints/thresholds for immune signaling in avoiding emergence of autoimmunity.



A	**Susceptibility**
	• Impaired tolerance induction • Impaired production of regulatory T cells • Altered immune signaling thresholds
B	**Initiation**
	• Suprathreshold concentration of autoantigens • Non-tolerized structure • Pro-immune context – infection, malignancy, exposure to adjuvants
C	**Propagation**
	• Acquisition of adjuvant properties by disease specific autoantigens • Increased autoantigen expression in the target tissue • Immune effector pathways generate/expose autoantigen, which further drives the immune response

FIG 50.1 Mechanisms of Autoimmunity. Autoimmune diseases result from a complex interplay of pathways and events that allow autoreactivity to manifest, and cause self-sustaining tissue damage. Mechanistically, it is useful to divide the process into three phases: (1) susceptibility phase—this is present before disease and is the phase in which one or several preconditions for later initiation are satisfied; (2) initiation phase—this is marked by the presence of autoimmunity, but precedes the diagnostic clinical phenotype; (3) propagation phase—this is marked by autoimmunity and tissue damage, in which immune effector pathways cause damage and provide antigen to drive the ongoing immune response.

Incomplete Thymic Tolerance Induction Predisposes to Autoimmunity

Significant insights into basic mechanisms can derive from the study of rare human phenotypes. This has been true for autoimmunity, where several monogenic disorders have defined important pathogenic principles. Autoimmune polyendocrinopathy syndrome type 1 (APS-1;also called APECED) is a

KEY CONCEPTS

Mechanisms Underlying Susceptibility to Autoimmunity

- Incomplete induction of tolerance in the thymus to peripherally expressed autoantigens (autoimmune regulator [AIRE] deficiency causing autoimmune polyendocrinopathy with candidiasis and ectodermal dysplasia [APECED])
- Impaired clearance and tolerance induction by apoptotic cells (*e.g.,* deficiency of C1q, C4, milk fat globule–epidermal growth factor (EGF) 8 [MFG-E8], Mer)
- Defective production of regulatory T cells (FOXP3 deficiency causing immune dysfunction/polyendocrinopathy/enteropathy/X-linked [IPEX] syndrome)
- Altered immune signaling thresholds (*e.g.,* cytotoxic T lymphocyte antigen-4 [CTLA-4] polymorphisms, protein tyrosine phosphatase, non–receptor type 22 [PTPN22] polymorphisms)

rare disease in which patients develop multiple autoimmune diseases, often beginning in childhood.[7] Although candidiasis and ectodermal dystrophy (including involvement of enamel and nails, as well as keratopathy) are features of the disease, the syndrome is characterized by striking autoimmunity directed against multiple different target tissues. Autoimmune processes include autoimmune hypoparathyroidism, Addison disease, autoimmune gastritis with pernicious anemia, type I DM, thyroid disease, autoimmune hepatitis, celiac disease, and gonadal failure. Numerous autoantigens have been defined as targets of autoimmunity in APS-1 and include enzymes specifically expressed in various endocrine tissues (*e.g.,* steroid 21-hydroxylase, specific for adrenal cortex; steroid 17α-hydroxylase, found in adrenal cortex and gonads; GAD65, found in pancreatic islets; and thyroid peroxidase). The genetic basis of APS-1 was mapped to a gene on chromosome 21q22.3, subsequently termed *AIRE* (for autoimmune regulator). *AIRE* expression is highest in the thymus, where it is expressed in medullary thymic epithelial cells. Several predicted structural features of the AIRE protein and its localization in nuclear dots suggested that the protein might be a transcriptional regulator, and significant evidence for this proposal was obtained *in vitro.* Several *AIRE*-deficient mouse models were subsequently generated, which allowed for the definition of important pathogenic pathways in APS-1 that may be broadly relevant to the mechanisms of autoimmunity in general. Thus mice deficient in *AIRE* developed various autoimmune phenotypes, resembling those found in human APS-1. These included multiorgan lymphocytic infiltration and autoantibodies, as well as autoimmune eye disease. In an elegant series of experiments, Anderson et al. demonstrated that AIRE regulates expression in thymic epithelial cells of various peripheral autoantigens normally expressed exclusively in endocrine target tissues.[8] Thus AIRE appears to regulate the ectopic expression in the thymus of tissue-restricted autoantigens and to provide an antigen source against which to establish central tolerance.[8]

These data demonstrate that expression of peripheral autoantigens in the thymus constitutes a major barrier to the subsequent development of autoimmunity against these peripheral sites. Although it is possible that similar principles apply to ubiquitously expressed autoantigens targeted in systemic autoimmune diseases, there are currently few data directly addressing this issue.

Impaired Clearance and Tolerance Induction by Apoptotic Cells: Susceptibility Defect in Systemic Autoimmunity

Although little is known in humans about the thymic pathways of tolerance induction to ubiquitously expressed autoantigens, there is accumulating evidence to suggest that in the periphery, apoptotic cells play an important role in providing a source of autoantigens against which the organism becomes tolerant.[9] Apoptotic cells are generally very efficiently cleared by phagocytic cells; these events are normally associated with the production of antiinflammatory cytokines and result in tolerance induction.[9] Interestingly, early components of the classical complement pathway (*e.g.,* C1q and C4) and cross-reactive protein (CRP) are required for efficient apoptotic cell clearance, with production of interleukin-10 (IL-10) and transforming growth factor-β (TGF-β). Therefore it is of particular note that homozygous C1q deficiency is associated with a striking susceptibility to SLE in humans, and this suggests that rapid, efficient, tolerance-inducing clearance of apoptotic cells may play a role similar to AIRE expression in the thymus in preventing subsequent emergence of autoimmunity to ubiquitously expressed autoantigens.[10] Additional support for this model comes from recent studies of milk fat globule–epidermal growth factor (EGF) 8 (MFG-E8), a glycoprotein secreted from macrophages that is required for the efficient attachment and clearance of apoptotic cells by macrophages and immature dendritic cells (DCs). MFG-E8 is also expressed in tingible-body macrophages in the germinal centers of secondary lymphoid tissues. Interestingly, many unengulfed apoptotic cells are present in the germinal centers of the spleen in *MFG-E8*–deficient mice, which develop a striking lupus-like phenotype (reviewed in Rai and Wakeland[11]). Together, the data strongly suggest that efficient, antiinflammatory clearance of apoptotic cells plays a central role in tolerance induction and prevention of autoimmunity.

Defective Production of Regulatory T Cells

Although there are pathways that *(i)* regulate autoantigen expression at sites of tolerance induction and *(ii)* guide autoantigens toward tolerance-inducing outcomes, these pathways alone are clearly insufficient to prevent the emergence of autoimmune disease. This fact is highlighted by the emergence of autoimmunity when regulatory T-cell (Treg) differentiation is abnormal in humans with IPEX syndrome, the human equivalent of the *scurfy* mouse. IPEX is a rare, X-linked recessive disorder characterized by type I DM, thyroiditis, atopic dermatitis, and inflammatory bowel disease (IBD) and is caused by mutations in the *FOXP3* gene.[12] FOXP3 is a member of the forkhead family of transcription factors and is essential for the development of $CD4^+$ Tregs, which have been shown to regulate the activation and differentiation of effector T cells at many different levels (Chapter 18).

Preliminary investigations into the role of Tregs in human autoimmune diseases have produced mixed results, but these cells likely play important roles in regulating disease onset and amplitude. As additional cell subsets and details about function emerge, this area will be clarified significantly.

Signaling Thresholds and Susceptibility to Autoimmunity

Several modulators of T-cell signaling have been defined as important susceptibility determinants in autoimmunity.[11] For example, cytotoxic T lymphocyte antigen-4 (CTLA-4) polymorphisms are associated with increased risk of a variety of autoimmune diseases, including type I DM, Graves disease, and RA. Similarly, a functional polymorphism in protein tyrosine phosphatase, non–receptor type 22 (PTPN22), has been identified as a major risk factor for several human autoimmune diseases, including SLE, RA, and type I DM. Although the exact mechanisms underlying susceptibility to autoimmunity remain unclear, in both cases, the polymorphisms appear to regulate the balance of stimulatory and inhibitory signaling in effector and Tregs, favoring effector T-cell activation.

Recent genetic studies have also suggested a potential role for innate immune sensors in autoimmunity, focusing attention on the critical balance between activation of the immune response to mitigate infectious damage and limiting the magnitude of the response to avoid immunopathology. Gain-of-function (GOF) variants of *IFIH1* (encoding melanoma differentiation-associated protein 5 [MDA5]) are associated with susceptibility to SLE.[13] This RNA helicase is essential for the detection of cytoplasmic viral RNA and activation of type I interferon (IFN) secretion by infected cells. The increased susceptibility to SLE with increased function of this antiviral pathway suggests that excessive IFN signaling may facilitate the development of autoimmunity. Key immune signaling pathways that protect the host from deleterious infectious and malignant challenges but potentially also enhance damage of self tissues in the process may, therefore, be important susceptibility factors in autoimmune diseases.

Thus there are many barriers to the development of autoimmunity, including effective tolerance induction in the thymus and the periphery, tightly regulated immune signaling, and homeostatic pathways of immunoregulation to limit anti-self responses should they occur. It is likely that the genetic susceptibility to autoimmunity in outbred humans represents an integrated threshold involving genes that regulate these various pathways—upon which environmental and stochastic events act to accomplish disease initiation and propagation.

PHASE 2: INITIATION

Initiation of an adaptive immune response requires presentation to T cells of suprathreshold concentrations of molecules with structure not previously tolerized by the host. One of the more persuasive models proposed to explain the persistence of potentially autoreactive T cells within the repertoire of the host is that of immunodominance of T-cell epitopes. This model provides major insights into the pathogenesis of autoimmunity.[11,14]

KEY CONCEPTS

Potential Mechanisms That Can Alter Antigen Processing to Reveal Potentially Cryptic Epitopes

- Modification of autoantigen processing through high-affinity binding to ligands or antibodies
- Distinct proteolytic machinery in the thymus and periphery—or differential modification of proteolytic activity
- Modification of autoantigen structure that modifies its processing by endogenous antigen-presenting cell (APC) machinery, generally through posttranslational modifications
- Novel proteolytic events not present in the normal APC pathways (*e.g.,* novel cleavage during cell death or damage or inflammation)
- Novel forms of autoantigens generated by mutation, truncation, or splicing

Dominance and Crypticity

Studies by Sercarz et al.[14] have stressed that although antigens contain numerous potential determinants that could be presented on major histocompatibility complex (MHC) class II molecules during antigen processing, not all determinants in a particular molecule are equally likely to be efficiently presented. Those determinants that are most efficiently presented are termed "dominant"; those that are not loaded onto MHC class II to a significant degree are termed "cryptic." For self antigens, it is likely that a constant set of dominant determinants are generated during antigen processing under most circumstances, with similar outcomes in the thymus and the periphery. Antigens processed by the "standard" pathway are, therefore, fully tolerized, with the T-cell repertoire purged of reactivity to the dominant self. However, the balance of dominant and cryptic epitopes presented during antigen processing is influenced significantly by changes of protein structure, which occur during various relevant physiological states[15] (Chapter 6). Several potential mechanisms that may alter antigen processing to reveal potentially cryptic epitopes are summarized below.

High-Affinity Binding of Antigen to Ligands or Antibodies

Several studies have demonstrated that antigen processing can be dramatically altered when the antigen binds with high affinity to a ligand or antibody. The study by Simitsek and colleagues (reviewed in Lanzavecchia[15]) demonstrated that presentation of T-cell determinants in tetanus toxin can be either enhanced or suppressed as a direct consequence of antibody modulation of antigen processing in human B-lymphoblastoid cells. Remarkably, a single bound antibody can simultaneously enhance the presentation of one T-cell determinant by more than 10-fold while strongly suppressing the presentation of a different T-cell determinant. Biochemical analyses have shown that both the suppressed and boosted determinants fall within an extended domain of antigen stabilized by this antibody during proteolysis. Thus ligand-induced changes in processing can destroy dominant determinants or reveal cryptic self determinants. Similar observations have also been made with numerous other antigen–antibody partners.[15]

Tissue-Specific Protease Expression

The study by Watts and associates (reviewed in Darrah and Rosen[16]) showed that a principal human leukocyte antigen–D related type 2 (HLA-DR2)–restricted epitope in myelin basic protein amino acids 85–99 (MBP85–99) contains a processing site for asparagine endopeptidase (AEP), with cleavage by AEP abolishing the epitope. AEP activity is, therefore, a critical factor in presentation of this epitope.[16] In human antigen-presenting cells (APCs), presentation of MBP85–99 is inversely proportional to the amount of cellular AEP activity, and inhibition of AEP greatly enhances presentation of the MBP85–99 epitope. Interestingly, both MBP and AEP are expressed in the thymus, AEP at abundant levels. These data suggest that this major epitope in neurological autoimmunity may not be presented under normal circumstances in the thymus as a result of destruction by AEP, therefore raising the potential for later presentation in the periphery in the setting of decreased AEP activity.

Posttranslational Modification of Autoantigen Structure

Autoantigens undergo a variety of posttranslational modifications, including phosphorylation, proteolytic cleavage, ubiquitination, transglutamination, citrullination, and isoaspartyl modification.[17] In several cases, autoantibodies recognize exclusively the modified form of the antigen (*e.g.,* RNA polymerase-II large subunit, serine/arginine-rich [SR] proteins, citrullinated vimentin, and other RA autoantigens), indicating that the modified forms of the molecules are important in driving the immune response. In addition, Doyle and Mamula[17] have demonstrated that post-translational modification of autoantigen structure may be more broadly relevant than can be appreciated by studying autoantibody specificity alone. They showed that although mouse immunization with a murine cytochrome c peptide (amino acids 90–104) resulted in no T- or B-cell response, immunization with the isoaspartyl form of this peptide resulted in strong T- and B-cell responses. The autoantibodies that were elicited recognized both the modified and the native forms of the antigen, but T cells only recognized the isoaspartyl form. Similar observations have also been made for several SLE autoantigens. The difficulty detecting and quantifying antigen-specific T cells in various autoimmune diseases may reflect their preferential recognition of subtly modified forms of autoantigen. This is an important area for future study—currently there is no systematic way to generate the relevant autoantigen forms.

Novel Antigen Cleavage During Cell Damage, Cell Death, or Inflammation

Recent studies have provided evidence that single proteolytic events early in antigen processing can play critical roles in defining the epitopes generated. For example, Watts and colleagues (reviewed in Darrah and Rosen[16]) have conclusively demonstrated that early cleavage by AEP determines subsequent proteolytic events. Modifications of the antigen that affect this early cleavage dramatically change the epitopes loaded onto MHC class II molecules.[16]

Inflammatory microenvironments can create significant potential to load distinct epitopes because unique proteolytic activities are present. Activated inflammatory cells constitute a major source of proteases, including various cytotoxic lymphocyte granule proteases (granzymes), as well as numerous neutrophil and monocyte granule proteases. It is of interest that numerous autoantigens targeted in systemic autoimmune diseases are substrates for these inflammatory proteases and that unique autoantigen fragments are generated through the activity of granzyme B and potentially other similar proteases.[16] Such autoantigen forms are not generated during other forms of cell damage or death, and similar activity is not observed against nonautoantigens. Thus novel proteolytic cleavage of intracellular autoantigens during activity of cytotoxic immune effector pathways may provide a source of cryptic epitopes not generated during homeostatic "tolerance-inducing" tissue turnover. Direct evidence that inflammatory protease-mediated revelation of cryptic epitopes is relevant to initiation of autoimmunity *in vivo* is still needed.

Autoantigen Alteration Caused by Mutation, Truncation, or Splicing

Since the final epitopes generated and loaded onto MHC class II molecules can be profoundly influenced by single, early cleavage events during antigen processing, relatively minor but critically placed changes in the primary structure of autoantigens can have the capacity to influence peptide selection. A study of the melanoma and vitiligo-associated autoantigens, tyrosinase-related proteins (TRPs) 1 and 2 has strikingly demonstrated that this mechanism may play an important role in generating immune responses to self and tumor antigens.[18] In this study, Engelhorn et al. examined whether mutated self gene products are more likely to initiate immunity and used a systematic approach to define some of the principles that determine this. They generated complementary DNA (cDNA) libraries encoding large numbers of random mutations in syngeneic TRPs. They then used an approach of DNA immunization of black mice to test the immunogenicity of the altered proteins encoded by the pools of mutated cDNA. Immunization with nonmutated proteins induced no detectable immune responses, consistent with establishment of tolerance to the full-length molecules. In contrast, the mutated cDNA pools elicited both autoimmune depigmentation and the ability to reject melanoma tumors. Additional analysis showed that autoimmunity resulted from mutations that altered autoantigen cell biology, particularly degradation rates and pathways. Mutations also created new T-helper (Th) cell epitopes and induced recognition of nonmutated but previously cryptic epitopes. Interestingly, mutations themselves did not form part of CD8 epitopes that drive the anti-self and antitumor immune responses. Mutated molecules that were immunogenic were frequently truncated, leading the authors to propose that inappropriately truncated self proteins can provoke autoimmunity when present in a proinflammatory environment. This study has provided an important mechanistic underpinning for the proposal that accumulated mutations have a role in the initiation of autoimmunity and that "autoimmunity" might target the cancer mutanome.

Recent work in the autoimmune rheumatic diseases (scleroderma and dermatomyositis) highlights the relationship between cancer and the autoimmune process. In these diseases, patients demonstrate an increased risk of cancer compared with controls. They also show a temporal clustering of cancer diagnosis around the time of dermatomyositis or scleroderma onset (reviewed in Shah[19]). Similarly, there is evidence for an association between SLE and cancer, particularly lymphoma, clustered within the first 2 years of SLE diagnosis.[20] These associations, both with timing of diagnosis and preferentially with specific tumor types, are strongly indicative of a nonrandom clustering of autoimmune processes and cancer, which is likely of mechanistic significance.

The mechanistic link between scleroderma and cancer was confirmed in a study that tested the hypothesis that an anticancer immune response may target a mutated autoantigen in the patient's cancer, which spreads to the wild-type version of the antigen to trigger a self-sustaining autoimmune disease (reviewed in Shah[19]). In this study of patients with scleroderma and cancer, genetic changes (either mutations or loss of heterozygosity) were identified in *POLR3A* (encoding RNA polymerase III large subunit) in the tumors of six of eight patients with anti-RNA polymerase III antibodies, whereas no such changes were identified in eight patients who lacked these antibodies. Anti-RNA polymerase III autoantibodies in patients with cancer demonstrated no specificity for the mutant form of the protein over the wild-type version, and analyses of peripheral blood lymphocytes identified T-cell reactivity against the mutant protein. These data suggest that somatic mutations arising in the context of cancer may prompt immune responses that mediate immunoediting as well as damage to nontumor host tissues.

It is, therefore, likely that somatic mutations acquired with age and their association with malignancy are important in the genesis of some forms of human autoimmunity. Additional studies to confirm this and elucidate the underlying mechanisms remain a high priority. However, the barriers to such studies in humans are very significant, as effective anticancer immunity may be phenotypically silent, and convenient technologies to quantify somatic mutation and specific immune responses in normal individuals will be needed to draw conclusions of causality.

Antigen Mimicry

The process of antigen mimicry (see below) has frequently been proposed as a potential initiator of autoimmune diseases.[21] This mechanism, particularly when isolated, is only likely relevant to those autoimmune processes clearly associated with antecedent infections, particularly infections that resolve spontaneously and subsequently recur upon reexposure to the offending agent. The mechanism may, however, also play a role in initiation of the autoimmune response in self-sustaining autoimmune processes but, in this case, requires that T-cell responses to the cross-reacting self antigen are initiated.

Foreign antigens, which often differ from their homologous self antigens in some areas, may, nevertheless, bear significant structural similarity to self antigens in other regions. Initiation of an immune response to the foreign antigen may generate a cross-reactive antibody response that also recognizes the self protein (antigen mimicry). When the antigen is a cell surface molecule, antibody-mediated effector pathways can lead to host tissue damage. Although the antibody response is cross-reactive with self molecules, the T cells that drive this response are generally directed at the foreign antigen, at least initially (see below). Diseases involving this sort of "antigen mimicry," therefore, tend to be self-limiting, although they can recur upon reexposure to the offending antigen. It is important to realize that antigen mimicry alone cannot explain self-sustaining autoimmune diseases, which are driven by self antigens and autoreactive T cells. In these cases, there is a requirement for overcoming T-cell tolerance to the self protein. The central issues in this regard are *(i)* how T-cell tolerance to self antigens might initially be broken, and *(ii)* once this has occurred, why these antigens continue to drive the immune response to self. The simultaneous liberation of self antigen in the presence of the cross-reactive antibody response has been proposed to play critical roles in this regard. For example, several studies have suggested that when a humoral response to a foreign protein is induced that cross-reacts with the self antigen, a strong Th-cell response specific for the self antigen can occur. The simultaneous liberation of significant amounts of self antigen in the setting of a cross-reactive antibody response may allow for effective presentation of cryptic epitopes in the self antigen to autoreactive T cells by activated cross-reactive B cells. If continued release of self antigen occurs, a specific, adaptive immune response to self will be sustained. Antigen release from tissues likely plays a critical role in driving this autoimmune process. Understanding the mechanisms of ongoing antigen release at sites of tissue damage in autoimmune disease (*e.g.*, unique pathways of cell injury and death) is a high priority for future work, as it provides a novel target for therapy (see below).

It is clear from the above discussion that extraordinary complexity is operative in initiation of the human autoimmune diseases. The patient population is genetically heterogeneous, the human immune system is complex and extremely plastic, and it interacts with a plethora of environmental stimuli and stochastic events. The simultaneous confluence of susceptibility factors and initiation forces to set off the self-sustained and autoamplifying process is, therefore, a rare occurrence. In contrast, once activation of autoreactive T cells has occurred, the ability of the immune system to vigorously respond to low concentrations of antigen, to amplify the specific effector response to those antigens, and to spread the response to additional antigens in that tissue, greatly reduces the stringency that must be met to keep the process going.

PHASE III: PROPAGATION

Principles of Amplification

One of the central features of human autoimmunity is the tendency of the process to amplify progressively with the accumulation of significant immune-mediated tissue damage. Furthermore, in the vast majority of cases, once such amplification begins, the process is very unlikely to resolve spontaneously. Autoantigens themselves can be very important in this phase, in terms of both acquisition of adjuvant properties and regulation of levels of expression. The essential features of amplification are a substrate cycle, in which antigen expression and adjuvant properties induce an immune response, which, in turn, induces increased antigen expression and tissue damage—and further drives the immune response. The importance of tissue-specific autoantigen expression in focusing such immune responses is only beginning to be recognized.

Acquisition of Adjuvant Properties by Disease-Specific Autoantigens

In spite of the fact that tens of thousands of molecules could be targeted by the immune system in autoimmunity, the number of molecules that are frequently targeted in the different phenotypes are markedly restricted—limited perhaps to 100 or so. This has led to the proposal that frequently targeted autoantigens may themselves have properties that make them proimmune. Work by Howard and associates (reviewed in Plotz[22]) provided important initial support for this proposal. They observed that the autoantigenic histidyl aminoacyl tRNA synthetase (HRS), which is targeted in autoimmune myositis (but not non–autoantigenic lysyl- and aspartyl-aminoacyl transfer RNA [tRNA] synthetases), is a chemoattractant to immature DCs and other leukocytes. The authors suggested that the selection of a self molecule as a target for an autoantibody response may be a consequence of proinflammatory properties of the molecule itself. They further suggested that modification of autoantigen structure during processes of cell damage or death may be critical in recruiting these additional functions of autoantigens.

Role of Innate Immune Receptors in Amplification

Several innate immune receptor systems that sense and transduce the signals from pathogen-associated molecular patterns (PAMPs) (*e.g.*, receptors of the Toll-like receptor [TLR] and retinoic acid-inducible gene I [RIG-I]–like receptor [RLR] families) may also play roles in transducing the proinflammatory properties of autoantigens.[6] Ligands for TLRs include both microbial and endogenous molecules, the latter group being particularly relevant to autoimmunity (see below). Microbial ligands include components of gram-positive bacteria, gram-negative bacteria, yeasts, and protozoans. For example, lipoteichoic acid and fungal products (*e.g.*, zymosan) signal through TLR2, lipopolysaccharide activates TLR4 signaling, dsRNA signals through TLR3, flagellin through TLR5, single-strand RNA (ssRNA) through TLR7 and TLR8, bacterial or viral DNA through TLR9, and *Toxoplasma* profilin through TLR11.[23] Although viral and bacterial nucleic acids are the most likely ligands for TLRs, accumulating data demonstrate that complexes containing endogenous nucleic acids are able to signal through TLRs. The exact nature and source of endogenous ligands for TLRs *in vivo* remains unclear; however, recent studies have demonstrated that components from stressed, injured, and dying cells may play critical roles in this regard.[6]

Working in several models, numerous investigators have now provided evidence that the frequent targeting of nucleoprotein autoantigens (which contain DNA or RNA) results from the ability of these nucleic acid components to ligate TLRs (reviewed in Kawasaki et al.[6]). For example, antichromatin immune complexes can activate DCs and B cells through ligation of both FcγR and TLR9. B-cell activation via TLR7 ligation by RNA-containing immune complexes has also been demonstrated. *In vivo* studies have linked these *in vitro* findings to the development of autoimmunity. For example, when *TLR9* deficiency is bred onto MRL-lpr mice—which are an excellent model of SLE—animals no longer develop autoantibody responses to chromatin. Interestingly, these animals, nevertheless, manifest the SLE phenotype—in some cases, more severely than the TLR9-sufficient animals. Similarly, when mice are rendered TLR7 deficient, the autoantibody response to Sm is markedly inhibited, and severity of the SLE phenotype is reduced. Reciprocally, overexpression of TLR7 is sufficient to induce an SLE-like disease (reviewed in Kawasaki et al.[6]). These data confirm that autoantigens frequently selected in different autoimmune phenotypes likely have the dual property of being able to simultaneously activate the innate and adaptive immune systems. The source, form, and uptake of nucleic acids clearly influence adjuvant activity. For example, bacterial and viral DNA and oligonucleotides with CpG motifs have significant adjuvant activity, whereas mammalian genomic DNA, in which CpG is usually methylated, has very poor adjuvant activity. In contrast, human DNA present within immune complexes in SLE serum activates plasmacytoid DCs effectively in a DNA-dependent way. Several potential explanations have been advanced to explain these observations.[6] First, FcγR-mediated uptake effectively captures self DNA bound by anti-DNA antibodies and directs it to the correct endosomal compartment for TLR signaling. Second, coligation of TLR9 and either B-cell receptor or FcγR alters the signaling threshold of immune complexes. Last, the difference lies in the nucleic acid itself, with additional modifications of DNA and RNA structure occurring in cells under different physiological circumstances (*e.g.,* cell death) and regulating nucleic acid binding to TLRs.[24] Recent studies have suggested that other sensors of PAMPs (*e.g.,* nucleotide-binding oligomerization domain [NOD]–like receptors [NLRs], RIG-like receptors) may play similar roles to TLRs in amplifying adaptive responses to specific intracellular autoantigens (*e.g.,* MDA5, interferon-γ–inducible protein 16 [IFI16]), but definitive evidence is not yet available.

The TLR–IFN interface has been recognized as critical in the propagation phase of systemic autoimmune diseases (reviewed in Hall and Rosen,[25] and Swiecki and Colonna[26]). Much attention has been focused on plasmacytoid dendritic cells (pDCs), a relatively rare class of immature DCs that can secrete large amounts of type I IFNs upon TLR ligation and that express TLR7 and TLR9 at high levels.[26] Recent studies in mouse models have demonstrated the ability of pDCs to alternately promote wound healing or chronic inflammation, depending on the predisposing genetic background. For example, nonspecific skin injury in wild-type mice (by tape stripping) leads to pDC recruitment, TLR7 and TLR9 recognition of nucleic acids, and transient expression of type I IFNs with subsequent wound healing.[27] In contrast, the same skin damage in a lupus-prone mouse strain results in chronic inflammation mediated by sustained type I IFN expression, which can be ameliorated with pDC depletion or TLR7/9 inhibition.[28] Extending these observations to human autoimmunity, IFN-α–inducing activity is abrogated by chloroquine or bafilomycin, agents that interfere with endosome acidification and TLR7 and TLR9 signaling. In addition, Rönnblom and colleagues (reviewed in Hall and Rosen[25]) demonstrated that when added to material from apoptotic or necrotic cells, autoantibodies from patients with SLE and Sjögren syndrome with specificity for DNA or RNA autoantigens induce striking IFN secretion. Type I IFNs have a broad set of functions that likely contribute to the feed forward, propagation phase of systemic autoimmune diseases.[6] For example, they *(i)* promote the differentiation of monocytes into mature DCs, which drive autoreactive T- and B-cell responses; *(ii)* increase target cell sensitivity to killing pathways; *(iii)* upregulate cytotoxic effector pathways; and *(iv)* upregulate expression of autoantigens, such as Ro52.

This general ability of autoantigens, particularly in the context of immune complexes, to stimulate secretion of IFN and other cytokines is likely an important principle in the initiation and propagation of autoimmunity.

Enhanced Autoantigen Expression in the Target Tissue

The striking association of specific autoantibody responses with distinct phenotypes suggests that autoantigen expression or form in specific target tissues may play an important role in both focusing the immune response and generating tissue damage. Unfortunately, very little is currently known about such parameters *in vivo* in relevant target tissues, both in normal and pathological circumstances.

Recent studies on human autoimmune myopathies have begun to provide important insights into this problem. Myositis-specific autoantigens are expressed at very low levels in control muscle but at high levels in myositis tissue, where antigen expression is at highest levels in regenerating muscle cells.[29] Interestingly, histidyl tRNA synthetase (HRS) expression is also found at high levels in lungs, and anti-HRS antibodies are associated with autoimmune myopathies with interstitial lung disease. Recently, 3-hydroxy-3-methylglutaryl-coenzyme A reductase (HMGCR) was identified as an autoantigen in patients with statin-associated autoimmune myopathy.[30] In addition to the induction of HMGCR protein expression by statin treatment of cultured cells, this group also demonstrated increased expression of this protein in regenerating muscle fibers of anti–HMGCR-positive patients. These data suggest that enhanced autoantigen expression in the target tissue may be a feature of disease propagation and that antigen expression during tissue repair may provide an ongoing antigen source to sustain and amplify tissue damage.

Defining whether similar principles are operating in other autoimmune diseases and elucidating the pathways of antigen expression and modification in relevant target tissues are an important areas of focus in future studies and may have important therapeutic potential.

ON THE HORIZON

- Precise clinical and molecular phenotyping of patients at various disease stages is critical for improving diagnosis, monitoring, and treatment of autoimmune diseases.
- Understanding mechanisms of disease amplification, propagation, and regulation will enable the development of effective targeted therapies.
- Understanding the mechanisms of human autoimmunity will likely provide important insights into the normal functioning of the immune system, particularly with regard to natural cancer immunity.

TRANSLATIONAL RESEARCH

The challenge in the next decade is to continue elucidating the underlying mechanisms of autoimmunity to improve diagnosis and treatment and enable more precise monitoring of these diseases. The existence of distinct phases in the development of autoimmune disease provides an opportunity to identify patients at risk of developing tissue damage before this occurs and potentially to interdict the process before the amplification cycle is established. Understanding natural mechanisms of regulation of disease amplitude, or in some circumstances, even disease resolution, will provide important opportunities for therapy. The role of the target tissue as an active participant, rather than a passive bystander, in the ongoing destruction will likely be understood in molecular detail and provide novel approaches to decreasing the amplitude of amplifying cycles. The identification of the precise biomarkers of all these events requires exceptional clinical phenotyping of patients early in the disease course, longitudinal analysis by centers of excellence that follow up large numbers of patients with similar phenotypes over time, and effective coupling to basic laboratory enterprise. Critical areas of future investigation relevant to diagnosis and therapy include clarification of the roles of genetic and epigenetic factors, interactions between the innate and adaptive immune responses, Tregs, and focus on the target tissue and antigen contributions to ongoing amplification.

MULTIPLE-CHOICE QUESTIONS

1. Antibodies directed against which of the following antigens has been shown to be associated with an increased risk of cancer in scleroderma?
   A. Topoisomerase
   B. RNA polymerase III
   C. Centromere
   D. Fibrillarin
   E. NXP-2

2. Which of the following autoantibodies is likely associated with systemic lupus erythematosus (SLE) propagation, based on the observation that it arises closest to the time of symptoms onset?
   A. Antinuclear
   B. Anti-La
   C. Antiphospholipid
   D. Anti-Sm

Systemic Lupus Erythematosus

Cynthia Aranow, Betty Diamond, Meggan Mackay

Systemic lupus erythematosus (SLE) is a systemic autoimmune disease characterized by the production of autoantibodies and a broad spectrum of clinical manifestations. It most commonly presents in women during their childbearing years. Although the etiology of SLE is unknown, both genetic and environmental factors contribute to loss of self-tolerance. Current therapeutic modalities are antiinflammatory and immunosuppressive.

EPIDEMIOLOGY

The American College of Rheumatology (ACR) classification (Table 51.1), created initially to classify this disease with multiple diverse manifestations, has undergone several revisions in efforts to improve sensitivity and specificity of the criteria.[1] The revised 1997 classification scheme is the most widely accepted instrument for "diagnosing" lupus; however, these criteria do not represent the full spectrum of disease. Patients fulfilling 4 out of the 11 criteria are classified with SLE with approximately 95% certainty, although many individuals who meet only two or three criteria may also be considered as having SLE. More recently, the Systemic Lupus International Collaborating Clinics (SLICCs) have proposed and validated a revised classification scheme that seeks to improve sensitivity and specificity by inclusion of a broader range of immunological and clinical criteria. A patient will satisfy the SLICCs classification of SLE if there is biopsy-proven lupus nephritis with an autoantibody (antinuclear antibody [ANA] or anti-dsDNA) or if a minimum of 4 predefined criteria are met (1 of these 4 criteria must be clinical, and one must be immunological).[2] During the childbearing years, the ratio of women to men with lupus is approximately 9:1. This ratio is less in younger and older populations, supporting a role for hormonal factors in disease induction. The majority of lupus presents during adulthood; approximately 20% of cases are in the pediatric population. Recent studies suggest that age at diagnosis may be increasing in some populations; mean ages at diagnosis reported since 2002 range from 31 years in Martinique and Brazil to 51.7 years in Wisconsin (United States) and 47 years in Sweden.

Lupus occurs throughout the world; susceptibility is linked to race and ethnicity as well as environmental exposures. Worldwide incidence rates vary from 1.9–8.7/100 000, and prevalence rates vary from 19.3–207/100 000;[3] however, incidence rates in African Americans, African Caribbeans, Hispanics, and Asians are approximately three times greater than in Caucasians. Although epidemiological data are scant, it appears that the incidence of SLE in Africa is lower. Data from animal models suggest this may be a consequence of a protective effect of malaria infection. Clinical manifestations, disease activity, damage accrual, mortality, and response to therapy are also modulated by ethnicity, and all studies support observations of increased disease activity, damage, and mortality in nonwhite populations (Table 51.2).[4]

Mortality

Increased awareness leading to earlier diagnoses, availability and use of immunosuppressive agents, and improved treatment for comorbid diseases have contributed to a dramatic decrease in mortality over the last half-century, with a 5-year survival rate of 50% in the 1950s to 96–99% in the past 5 years.[5] Despite this increase in survival, lupus patients continue to suffer significant morbidity and mortality related to disease and medication effects. Compared with the general population, risk of death is reported as 2–5 times higher in lupus patients, with standardized mortality rates as high as 6.7 and 7.8 in SLE cohorts with lupus nephritis. Overall, mortality is modulated by gender, ethnicity, race, geographical location, disease comorbidity, age at diagnosis, and the presence of lupus nephritis or end-stage renal disease. Generally, highest mortality rates are associated with male sex, black race, and active lupus nephritis. The leading causes of death include cardiovascular disease, infection, and active SLE; the order of frequency depends on the population reported. A bimodal distribution of death has been well recognized; early deaths often result from infections or active disease, whereas deaths occurring later in the course of disease are frequently attributed to end-stage organ damage and cardiovascular disease, usually in the setting of inactive disease. Both cardiovascular disease and organ failure are associated with damage accrued from recurrent SLE disease activity and medication effects.

DAMAGE

With improved survival, the impact of comorbid conditions has become increasingly important. Patients may accrue irreversible damage over time resulting from active disease and/or toxicities of medications. The SLICCs/ACR Damage Index (SDI) is a validated instrument to measure damage. Damage accumulates over time and is associated with poorer quality of life as well as increased morbidity and mortality. Renal, musculoskeletal, and cardiac domains are important contributors to damage. There is increased awareness of cardiovascular disease in SLE. As discussed below (cardiac involvement: coronary artery disease), events attributable to atherosclerotic disease occur significantly more frequently in lupus cohorts compared with their age-matched controls. Traditional risk factors, *e.g.*, hypertension, hyperlipidemia, physical inactivity, and impaired glucose control, are enriched in lupus patients. However, the risk of cardiovascular events continues to

TABLE 51.1 American College of Rheumatology Criteria for Systemic Lupus Erythematosus

Criteria	Description
Malar rash	Fixed malar erythema, flat or raised
Discoid rash	Erythematous raised patches with adherent keratotic scaling and follicular plugging; atrophic scarring may occur in older lesions
Photosensitivity	Skin rash as an unusual reaction to sunlight, by patient history or physician observation
Oral ulcers	Oral and nasopharyngeal ulcers, usually painless, observed by physician
Arthritis	Nonerosive arthritis involving two or more peripheral joints, characterized by tenderness, swelling, or effusion
Serositis	Pleuritis (convincing history of pleuritic pain or rub heard by physician or evidence of pleural effusion) *or* Pericarditis (documented by electrocardiogram or rub or evidence of pericardial effusion)
Renal disorder	Persistent proteinuria > 0.5 grams per day or > than 3+ if quantification not performed *or* Cellular casts may be red cell, hemoglobin, granular, tubular, or mixed
Neurological disorder	Seizures—in the absence of offending drugs or known metabolic derangements, *e.g.,* uremia, ketoacidosis, or electrolyte imbalance *or* Psychosis—in the absence of offending drugs or known metabolic derangements, *e.g.,* uremia, ketoacidosis, or electrolyte imbalance
Hematological disorder	Hemolytic anemia—with reticulocytosis *or* Leukopenia (<4000/mm^3 total on two or more occasions) *or* Lymphopenia (<1500/mm^3 on two or more occasions) *or* Thrombocytopenia (<100 000/mm^3 in the absence of offending drugs)
Immunological disorder	Anti-ds DNA: antibody to native DNA in abnormal titer *or* Anti-Sm: presence of antibody to Sm nuclear antigen *or* Positive finding of antiphospholipid antibodies based on (1) an abnormal serum level of immunoglobulin G (IgG) or IgM anticardiolipin antibodies; (2) a positive test for lupus coagulant using a standard method; or (3) a false-positive serological test for syphilis known to be positive for at least 6 months and confirmed by *Treponema pallidum* immobilization or fluorescent treponemal antibody absorption test
Antinuclear antibodies	An abnormal titer of antinuclear antibody by immunofluorescence or an equivalent assay at any point in time and in the absence of drugs known to be associated with "drug-induced lupus" syndrome

be greater in lupus patients compared with their healthy peers even after controlling for traditional risk factors, suggesting that lupus *per se* confers a risk for atherosclerotic events.

IMMUNOPATHOGENESIS

The immune system is designed to protect the host against foreign pathogens and to remove cellular debris without damaging self. With their universal production of autoantibodies and characteristic pathological findings of inflammation, vasculitis, vasculopathy, and immune complex deposition, SLE patients display a failure to maintain immune tolerance and immune homeostasis. The heterogeneity of disease manifestations reflects the multiplicity of genetic, hormonal, and immune abnormalities and the diversity of environmental triggers or modifiers contributing to clinical disease (Table 51.3). Progression from initial autoreactivity to clinical disease occurs over time (Fig. 51.1), with the first detectable immune abnormalities of either the presence of serum autoantibodies or the increased expression of interferon (IFN)-inducible gene in blood cells (the IFN signature).

Autoantibodies

ANAs are present in over 98% of patients diagnosed with SLE. Their presence is not specific to SLE, as they are observed in patients with other autoimmune diseases, malignancies, and viral (hepatitis) and parasitic (malaria) infections as well as in response to environmental triggers such as therapeutic agents (see section on drug-induced lupus, below). Furthermore, ANAs are found in low titer in 5% of the general population, with prevalence increasing with age. Common ANA specificities found in lupus patients include double-stranded (ds) DNA, single-stranded (ss) DNA, extractable nuclear antigens (Sm, RNP, Ro, and La), histones, and chromatin. Specific ANAs are associated with disease subsets such as anti-Ro antibodies with subacute cutaneous and neonatal SLE, anti-dsDNA, and anti-C1q antibodies with renal disease.[6] Most autoantibody titers do not correlate with disease activity; anti-ds DNA antibodies are a notable exception. Their fluctuation with disease activity suggests a pathogenic role for this autoantibody, and monitoring their titer helps to predict impending disease flare in some patients.

The Predisposed Host: Genetic Contributions

SLE is a multigenic disease. Most disease-associated alleles are present in healthy individuals. Only when multiple alleles are present, along with an appropriate environmental trigger, will a lupus-like phenotype arise. Familial disease clustering and a higher disease concordance in monozygotic than dizygotic twins suggest both an underlying genetic susceptibility and the importance of environmental or epigenetic factors. Cell types with highest expression of genes for which there are SLE susceptibility alleles are B cells and dendritic cells (DCs), suggesting that these cell lineages may be drivers of disease. This is an intriguing hypothesis, as it suggests that alterations in B-cell tolerance mechanisms and alterations in antigen presentation to T- effector and T-regulatory cells and altered cytokine production are central to disease pathogenesis.

Presumed susceptibility genes identified in humans include those affecting lymphocyte activation, proliferation and apoptosis,

cytokine production, antigen presentation, and clearance of apoptotic debris. Many of these genes are also implicated in susceptibility to other autoimmune diseases (*e.g., CTLA4* in Graves disease and type 1 diabetes, *PTPN22* polymorphisms in rheumatoid arthritis and type 1 diabetes).[7,8] Genome-wide association studies (GWASs) and genome-wide linkage analyses have utilized high-throughput techniques to study hundreds of thousands of single nucleotide polymorphisms (SNPs) in individual patients with SLE and have yielded approximately 50 SLE-associated susceptibility loci,[9] some of which are of particular relevance in ethnic and racial groups (Chapter 33).

Genes Associated With Antigen Presentation

Polymorphisms of major histocompatibility complex (MHC) genes determine the peptides of self and foreign antigens presented within MHC molecules that select the naïve T-cell repertoire. Human leukocyte antigen (HLA)-DR2 haplotypes in African American, African, Taiwanese, and Korean populations and HLA-DR3 haplotypes in Caucasian populations have been associated with a two- to threefold increased risk for developing SLE.[10] Associations between anti-Ro antibodies and HLA-DR3 and anti-La antibodies and HLA-DR25 are consistent with the concept of antigen-driven processes involving T-cell recognition. The association of HLA with SLE is not as dominant as with other autoimmune disease, suggesting that the T-cell response may dictate autospecificity (as above) but is less important in determining risk of disease.

Genes Associated With Impaired Clearance of Apoptotic Debris

Patients with severe deficiencies of C2, C4, and C1q display disease risks of 10%, 75%, and 90%, respectively, for SLE.[11] Reduced uptake of apoptotic cells has been implicated in disease initiation in murine models of SLE and is seen histopathologically in lymph nodes of lupus patients.[12] Though rare, individuals homozygous for null alleles of C2, C4, and C1q are at significantly increased risk. Polymorphisms of mannose-binding lectin (MBL) and C-reactive protein (CRP)—acute-phase reactants that facilitate opsonization and phagocytosis of immune complexes, apoptotic debris, and microbes—also associate with SLE susceptibility; MBL haplotypes appear to be more important in Chinese and Spanish populations than in Caucasians. *TREX1* encodes a 3′ repair exonuclease that monitors DNA synthesis; TREX1 deficiency leads to accumulation of endogenous DNA and is associated with increased expression of IFN and autoimmunity. *ITGAM* encodes the α-chain of an integrin adhesion molecule that binds C3b fragments and other proinflammatory molecules. GWASs have identified associations of *TREX1* and *ITGAM* variants with and SLE susceptibility in European populations. *ITGAM* has also been reported as a susceptibility gene in African American and Hispanic populations but not in Asian populations.[9]

The Fcγ receptors—FcγR1 (CD 64), FcγRII (CD32), and FcγRIII (CD16)—have different binding affinities for immunoglobulin (IgG) and immune complexes as well as different cell-specific expression and function. FcγRI, FcγRIIa, and FcγRIIIa and IIIb are all activating receptors. Cross-linking these receptors by immune complexes results in degranulation, phagocytosis, antibody-dependent cellular cytotoxicity, cytokine gene transcription, and release of inflammatory mediators by myeloid cells. Substitutions of one or more amino acids in the activating FcγR genes—arginine (R) for histidine (H) at position 131 in γFcγRIIa and phenylalanine (F) for valine (V) at position 158 in γFcγRIIIa—results in decreased affinity for IgG immune complexes. Because apoptotic debris is opsonized by antibody to promote clearance, such deficiencies may lead to immune activation by apoptotic debris. Associations between the γFcγRIIa R131H allele and disease susceptibility or nephritis occur in Brazilian, Thai, Korean, German, and African American populations, and FcR polymorphisms may also predict a therapeutic response to immunobiological agents such as rituximab.[13] γFcγRIIIa F158V and γFcγRIIIb NA2/NA2 polymorphisms are reported to associate with disease susceptibility in Dutch, Korean, Thai, and Caucasian populations (reviewed in Mackay et al., 2006).[14] In contrast, FcγRIIb is an inhibitory receptor. Engagement of FcγRIIb on DCs delivers an inhibitory signal. Cross-linking of FcγRIIb and the B-cell receptor (BCR) results in decreased intracellular calcium flux with decreased B-cell activation and proliferation. The FcγRIIb I232T allele leads to the inability of the receptor to enter lipid rafts and perform its inhibitory function. This allele is associated with SLE in Asian populations,[15] and dysregulation of FcγRIIB expression on activated memory B cells has been reported in SLE patients.[14]

Genes Associated With Lymphocyte Activation, Proliferation, and Function

Several SLE risk genes have been implicated in the regulation and activation of lymphocytes. *BLK, LYN,* and *BANK1* encode the tyrosine-kinase proteins Blk and Lyn and B-cell scaffold protein with ankarin repeats; all are associated with intracellular signaling pathways. *ETS1* and *IKZF1* encode transcription factors and are believed to play a role in B-cell differentiation and self-tolerance. Cytotoxic T lymphocyte antigen-4 (CTLA-4) is upregulated on T cells after activation and dampens inflammatory responses. It has a higher affinity than CD28 for B7.1 (CD80) and B7.2 (CD86), thereby competitively inhibiting engagement of CD28 and blocking the costimulatory signal required for T-cell activation. CTLA-4 ligation of B7 also activates indoleamine dioxygenase (IDO) expression, an enzyme involved in tryptophan metabolism, and diminishes T-cell proliferation. Finally, CTLA-4 is critical for activation of regulatory T cells. In CTLA-$4^{-/-}$ mice, an uncontrolled, lethal inflammatory response occurs. CTLA-4 alleles with decreased production of soluble CTLA-4 are implicated in the pathogenesis of several autoimmune diseases, including Sjögren disease, ulcerative colitis, psoriasis, type 1 diabetes, and multiple sclerosis as well as SLE.[16]

The *PTPN22* gene encodes a tyrosine phosphatase that has been suggested to downregulate T-cell and B-cell receptor (BCR) activation, although the precise role of polymorphic PTPN22 I disease pathogenesis remains unresolved. *A PTPN22* polymorphism resulting in diminished ability to control T-cell antigen receptor activation has been reported in SLE and other autoimmune diseases, suggesting a common mechanism of immune dysregulation. The PTPN22 risk allele has also been associated with reduced type I IFN production by myeloid cells after activation of Toll-like receptor (TLR) 7.

Genes Encoding Cytokines and Chemokines

IFN regulatory factor 5 gene (*IRF5*) encodes a critical transcription factor in the type I IFN pathway; the *IRF5* locus has the strongest association with SLE outside of the MHC region. Four allelic variants have been identified in multiple ethnically diverse populations. Variants of the signal transducer and activator of transcription factor 4 protein (*STAT4*) gene have also been associated with SLE susceptibility in GWASs of Caucasian and Asian populations. There are data suggesting interaction between IRF5 and STAT4, and the presence of one or more risk alleles of the two genes may confer increased susceptibility. IL-1 receptor-associated kinase 1 (*IRAK1*) and methyl-CPG-binding protein 2 (*MECP2*) genes are both found on the X chromosome. IRAK1 regulates multiple pathways in innate and adaptive immune responses, including the link between immune complexes, TLR signaling, T-cell receptor (TCR) signaling, and IFN production. Monocyte chemoattractant protein (MCP-1) is a potent chemoattractant for monocytes, memory T cells, and natural killer T cells. MCP-1 expression is upregulated in renal tubular cells, and glomeruli in lupus nephritis and urine levels of MCP-1 are increased in patients with active lupus nephritis. An MCP-1 polymorphism resulting in increased MCP-1 production has been associated with SLE nephritis.[17] Polymorphisms in the tyrosine kinase-2 (*TYK2*) gene are associated with increased expression of type I IFNs (IFN-α, IFN-β) in SLE. IFN-α-regulated genes are highly expressed in peripheral blood cells from SLE patients compared with healthy controls (the IFN signature).[18] IFN-α mediates maturation of DCs and monocytes, increasing the capacity for T-cell activation, and promotes B-cell differentiation and Ig class switching. However, in two murine models of lupus, decreases in type I IFNs unexpectedly led to worsening disease, consistent with numerous studies showing that type I IFNs have both pro- and antiinflammatory effects on innate and adaptive immune responses and suggesting that the effect of IFN-α on autoimmunity is complex.

Multiple polymorphisms in the *IL10* gene have been reported, with conflicting results with respect to SLE susceptibility. A meta-analysis of 15 studies concluded that some *IL10* polymorphisms do associate with SLE, but their importance is modulated by ethnic background.[19]

In the NZB/W murine model, a tumor necrosis factor (TNF) allele associated with low production is linked with disease, and treatment with TNF decreases autoantibody production. Consistent with this observation, TNF blockade for rheumatoid arthritis or inflammatory bowel disease can lead to autoantibody production and infrequently to frank lupus. Several polymorphisms for genes encoding TNF-α and -β (lymphotoxin-α) have been associated with SLE; these associations are also influenced by ethnicity.[20]

Genes Associated With Cell Survival

Fas ligand (expressed on activated T cells) binding to Fas (CD95) stimulates a signaling pathway resulting in apoptotic death of the Fas-expressing cell. Fas-induced apoptosis of activated cells contributes to the elimination of autoreactive B and T lymphocytes. Lymphopenia in SLE has been associated with increased Fas expression on lymphocytes, and Fas and Fas ligand alleles have been linked to disease susceptibility.[21] Whereas lack of Fas expression in mice leads to an SLE-like phenotype, lack of Fas expression in humans is associated with a lymphoproliferative disease that does not share autoantigen specificities and target organs with SLE.

Bcl-2 family genes encode intracellular proteins that are either pro- or antiapoptotic. Increased expression of Bcl-2, an antiapoptotic molecule, leads to a lupus-like serology and nephritis in mice with certain genetic backgrounds. Increased intracellular levels of Bcl-2 have been reported in SLE, particularly in Chinese and Mexican populations. The combination of a Bcl-2 susceptibility allele and interleukin-10 (IL-10) susceptibility allele confers a 40-fold increased risk of SLE, demonstrating that *infelicitous* combinations of risk alleles potentiate risk.[22]

Genes Regulating Target Organ Damage

Only a few genes are known to regulate the vulnerability of target organs, the kidney in particular, to autoimmune attack. In mice, genes encoding kallikreins, which upregulate bradykinins, have SLE susceptibility alleles. In human studies a risk allele for ABIN1, which regulates nuclear factor (NF)-κB activation, can lead to greater kidney disease. Two risk alleles of APDOL1 are particularly common in the African American population and are thought to contribute to the increased severity of renal disease in this population.

Epigenetic Contributions

Epigenetic regulation plays a determining role in gene activation. Major epigenetic influences in SLE involve DNA methylation at cytosine-guanine nucleotides (CpG methylation) and histone posttranslational modifications (lysine acetylation or methylation, phosphorylation of serine or threonine, arginine methylation).[23] SLE susceptibility and autoantibody production is associated with DNA hypomethylation.[24] Several drugs known to induce a lupus-like disease (procainamide, hydralazine) also cause decreased DNA methylation. A landmark study of high-throughput analysis of DNA methylation in discordant twins demonstrated greater DNA hypomethylation in the affected siblings.[25] It is not surprising that genes encoding integrins, NGAL, CD40 ligand, IFN-γ receptor, and IL-6 are among the hypomethylated genes in SLE. Mechanisms for hypomethylation remain unclear; decreased efficacy of DNA methyltransferases (DNMTs) and overexpression of microRNAs (miRNA) that interfere with DNMT activity have been proposed.[26]

Vitamin D has been shown to contribute to the regulation of the epigenome. Vitamin D levels are low in many lupus patients, but the relationship of vitamin D levels to disease risk or disease severity remains controversial.[27]

Inflammation itself may alter the epigenome; some studies suggest that the metabolic modulator metformin can reverse some of the inflammation-induced alterations. Recent studies show that metformin can reduce murine lupus, although the mechanism for this therapeutic effect is not completely clear.

B Cells

B-Cell Selection

The process of immunoglobulin variable region gene rearrangement produces large numbers of self-reactive B cells. Most B cells displaying self-reactive immunoglobulin are deleted centrally in the bone marrow and at subsequent checkpoints in the periphery (Fig. 51.2), so the frequency of autoreactive cells decreases from ~75% in immature B cells in the bone marrow to ~20% in the mature naïve B-cell population in healthy individuals. Many of the autoreactive B cells in the naïve population are normally suppressed by anergy induction. Several of these checkpoints appear deficient in SLE. The IgM cross-reactive autoantibodies made by these remaining autoreactive mature naïve B cells are thought to facilitate clearance of apoptotic cells, decreasing the development of potentially pathogenic T- and B-cell responses to self-antigens. When IgM autoreactive antibodies are missing in mice, a lupus-like phenotype develops.

Another important peripheral checkpoint is entry into the T-cell-dependent, long-lived memory compartment. B cells with the 9G4 idiotype express antibodies encoded by the *VH4-34* gene, reactive with *N*-acetyllactosamine (NAL) determinants of glycoproteins on blood group antigens targeted by cold agglutinins, gangliosides, gastrointestinal (GI) mucins, glycolipids, and CD45 on B lymphocytes.[28] 9G4 B cells are reported to be present in 5–10% of the naïve B-cell population in healthy donors as well as in the IgM memory compartment. However, 9G4 B cells are excluded from the T-cell–dependent IgG memory and plasma cell populations, suggesting that these autoreactive cells fail to cross a developmental checkpoint after activation in normal individuals. Evaluation of tonsillar biopsies and spleens from healthy donors shows that the frequency of germinal centers with $9G4^+$ cells is less than 1%, implying that negative selection of autoreactive cells occurs at the transition of naïve to germinal center B cells. In contrast, tonsillar biopsies from SLE patients demonstrate that 15–20% of germinal centers are positive for autoreactive 9G4 B cells. This study, as well as others, suggests that checkpoints exist for entry into and exodus from the germinal center response and that these may be altered in SLE.

For example, it is clear that some pathogenic autoantibodies are not derived from natural autoantibodies. Back mutation of several anti-DNA antibodies to their germline-encoded precursors has identified nonautoreactive precursors. The failure of censoring mechanisms in germinal centers to prevent the maturation of autoreactive cells may reflect intrinsic B-cell abnormalities or abnormalities in costimulatory molecules, cytokines (such as B cell–activating factor [BAFF]; see below), follicular DCs, or T-cell, B-cell interactions.

B-Cell Signaling

Hyperactive B-cell responses to immunological stimulation are implicated in the production of pathogenic antibodies. SLE B cells have increased intracellular Ca^{2+} flux in response to BCR signaling,[29] partially due to FcγRIIb dysfunction (Ile 232 Thr).[15]

The intracellular protein tyrosine kinase Lyn has both positive and negative effects on BCR signaling. Decreased expression of Lyn results in increased intracellular Ca^{2+} flux and B-cell hyperactivity. Correspondingly, Lyn expression is decreased in resting and activated B cells in one-half to two-thirds of SLE patients, suggesting that Lyn may modulate negative regulation of BCR signaling in human disease. In contrast, a Lyn mutation in mice leading to increased expression results in autoantibody production and severe glomerulonephritis, suggesting that balanced Lyn expression is critical to tolerance pathways.

B-Cell Rescue

B lymphocyte stimulator (BAFF; also known as BLyS) is a member of the TNF family and participates in B-cell maturation and survival. BAFF enhances survival of B cells through engagement of several receptors–BCMA, BAFF-R, and TACI. High levels of this cytokine allow survival of autoreactive B cells in mice, resulting in a lupus-like disease (reviewed in Liu and Davidson).[30] Evidence supporting a role for BAFF in autoreactive B-cell rescue and human SLE includes the elevated levels seen in lupus patients, associations of BAFF levels with autoantibody titers, and, in some reports, correlations with disease activity. Recently belimumab, a monoclonal antibody directed against soluble BAFF,

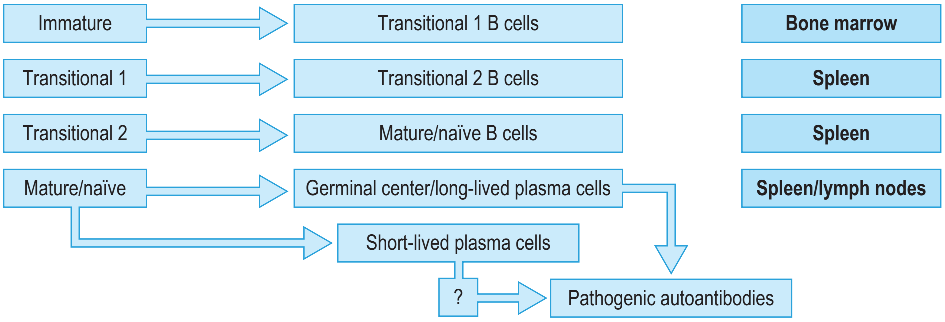

FIG 51.2 Autoreactive B-Cell Checkpoints. There are tolerance checkpoints at every stage of B-cell activation and maturation. How many checkpoints need to be breached to achieve a pathogenic state and clinical disease is not known.

has been shown to increase the percentage of ANA-positive B cells that are anergic in SLE patients.

Interactions between CD40 (B cell) and CD40 ligand (CD40L, T cell) are essential for B-cell proliferation, differentiation of memory cells into plasma cells, and germinal center formation. Immature autoreactive B cells can be rescued from antigen-induced apoptosis by engagement of CD40 or by IL-4.[31] SLE T and B cells have upregulated CD40L, providing a critical molecule to mediate B-cell rescue. The combination of IL-17 and BAFF facilitates B-lymphocyte proliferation and maturation. This combination can serve as an alternative stimulatory signal for B-cell activation and can replace CD40/CD40L interactions. Therefore in a permissible and proinflammatory cytokine milieu, B-cell activation and autoantibody production may occur in the absence of cognate T-cell help.[32] These studies are consistent with the increased numbers of plasmablasts present in blood of lupus patients with active diseases and with the increased numbers of class-switched CD27-negative B cells in blood of lupus patients.

B-Cell Pathogenicity Unrelated to Antibody Production

An essential role for B cells in SLE that is independent of antibody production is demonstrated by the T-cell activation, kidney inflammation, and increased mortality in MRL/lpr lupus-prone mice that lack the ability to secrete antibody and the absence of such cells in mice that lack B cells. B cells are efficient antigen-presenting cells; B cells with self-reactive specificity that have escaped tolerance are likely to present self-antigen to autoreactive T cells. This may explain, in part, the beneficial effects of treatment with rituximab, a B-cell–depleting drug, in SLE as autoantibody levels remain unaffected.

Neutrophils

An important link exists between neutrophils and autoimmunity. Neutrophil extracellular traps (NETS) are chromatin filaments released from neutrophils to trap microbes. In addition to microbial peptides, NETS also contain neutrophil peptides, including neutrophil-encoded antimicrobial peptide LL37 (cathelicidin). Circulating DNA-containing immune complexes from lupus patients have been shown to contain peptide LL37. These combined DNA/LL37 immune complexes are potent TLR9 stimulants, resulting in production of IFN-α by plasmacytoid DC (pDC).[33] Moreover, anti-RNP antibodies also induce "NETosis" in a process that is dependent on TLR7 and FcγRIIa signaling.[34] Thus it is possible that autoantibodies accelerate NET formation and increase formation of DNA/LL37 immune complexes and pDC production of IFN-α. These studies confirm earlier work that described a "granulocyte signature" with significant upregulation of granulocyte-specific transcripts within peripheral blood mononuclear cells in pediatric SLE patients.[35]

Dendritic Cells

DCs recognize pathogens through membrane pattern recognition receptors (PRRs) and are a critical component of the immune system connecting innate and adaptive immune responses.[36] They can be tolerogenic or highly inflammatory due to their high expression of costimulatory molecules. DCs function normally as surveillance cells, phagocytizing cellular debris and determining whether there is cause for alarm. PRRs on DCs bind pathogen-associated molecular patterns (PAMPs) and damage-associated molecular patterns (DAMPs) that are present in sterile inflammation. After internalization of the PAMPs or DAMPs, endosomal TLRs are activated by nucleic acids and other ligands. Enhanced IFN-α in SLE pathogenesis is now well described; the primary cells responsible for IFN-α production are pDC. TLR7 or TLR9 activation with RNA and DNA, respectively, induces immature DC to differentiate to immunocompetent, IFN-α-producing DC that have wide-reaching effects on T cells, B cells, neutrophils, and monocytes. Of note, type I IFN increases plasmablast differentiation favoring short-lived plasma cells over germinal center matured long-lived plasma cells. Plasmacytoid dendritic cells (pDC) have been demonstrated in skin and renal lesions, and upregulation of the "IFN signature" is observed in many, but not all, SLE patients and has been associated with disease activity. A number of susceptibility genes identified through GWASs are associated with IFN pathways in SLE including *IRF5, IRF7,* and *STAT4.*

T Cells

T cells are critical in the abrogation of self-tolerance by providing help to autoreactive B cells and facilitating the production of somatically mutated, high-affinity, pathogenic autoantibodies. Lupus patients can exhibit T-cell phenotypes consisting of increased numbers of $CD3^+CD4^-CD8^-$ T cells, increased Th17 cells, T-follicular helper (Tfh) cells, and decreased numbers or function of T regulatory cells (Tregs).[37] Additionally, lupus T cells display increased expression of activation markers and abnormal TCR signaling responses. A substitution of TCR ζ-chain by the γ-chain of the Fc receptor results in increased intracellular influx of Ca^{2+} after TCR stimulation and a concomitant decrease in IL-2 production, disfavoring the induction of Tregs.

Self-tolerance is maintained in part by the suppressive actions of Treg. "Natural" Tregs arise *de novo* in the thymus, whereas "induced" Tregs evolve from naïve T cells exposed to IL-2 and transforming growth factor (TGF)-β in the periphery. These cells are characterized by high surface expression of the IL-2 receptor α-chain, CD25, and high levels of FOXP3 intracellularly. Tregs act together with tolerogenic DC to maintain a steady state of immature DC. In contrast, effector T cells can secrete IFN-γ and IL-17 that promote immature DC differentiation to immunogenic DC capable of secreting IL-1, IL-6, IL-12, and TNF-α and can activate autoreactive T cells, thereby establishing a feedback loop with impaired Tregs and activation of autoreactive T cells.[38] Studies demonstrate alterations in Tregs in patients with SLE. Some have demonstrated reduced numbers and altered function of peripheral $CD4^+CD25^+$ $FOXP3^+$ cells in patients with active disease, whereas others fail to identify a defect.[39]

HORMONAL INFLUENCES

The most compelling evidence for the role of sex hormones in SLE is the observation that lupus preferentially affects women of childbearing age. The female-to-male ratio is 2:1 before menarche, 8–9:1 in the fourth decade, and 2:1 after menopause. Numerous case reports and studies of disease flares correlating with pregnancy, menstruation, and use of oral contraceptives containing high doses of estrogen suggest a role for estrogen in disease activity. A significant correlation between plasma levels of estradiol and clinical disease activity and increased α-hydroxylation of estrogen in SLE yielding the more active metabolite 16α-hydroxyestrone are also reported.[40] No significant differences in levels of sex hormones (including estrogen, testosterone, prolactin) are noted in male SLE patients, suggesting that the development of SLE in females may be more closely related to sex hormones than in men. Randomized controlled studies of estrogen in SLE suggest that the use of exogenous estrogen in patients with stable disease may be safe; however, a subset of patients appears to have an estrogen-sensitive disease. Mild to moderate flare rates were significantly increased in postmenopausal women treated with hormone replacement therapy.

Most of what we understand about hormonal modulation of B-cell development comes from mouse studies.[31] Estrogen treatment of NZB/W and MRL/*lpr* mice or castration of male lupus-prone mice exacerbates disease, whereas oophorectomy of female mice ameliorates disease. Treatment of lupus-prone mice with the selective estrogen receptor modulator tamoxifen also ameliorates disease.

Estrogen and prolactin promote the loss of B-cell tolerance in nonautoimmune mice. Estrogen results in diminished B-cell responsiveness to BCR cross-linking and in less stringent negative selection. Additionally, estrogen has also been reported to inhibit activation-induced T-cell death by downregulation of Fas ligand expression, thereby permitting increased numbers of autoreactive T cells.[41] Emerging data suggest that estrogen receptor signaling promotes differentiation of DC into immune-competent DC through increased expression of the transcription factor IRF4.[42]

Elevated prolactin levels are reported in 20% of patients with SLE, and increased prolactin exposure in lupus-prone mice exacerbates disease activity. Whereas treatment of patients with bromocriptine yielded equivocal results, treatment of NZB/W lupus mice with bromocriptine results in improved survival. Transmembrane prolactin receptors are present on a variety of cells, including T and B cells. Upregulation of both Bcl-2 and CD40 on B cells and CD40L on T cells occurs in response to prolactin, identifying pathways that may be involved in the prolactin-mediated rescue of autoreactive B cells.

Data on the microbiome demonstrate that sex hormones can modulate its composition. Studies in murine lupus suggest that androgens generate a microbiome that prevents the development of lupus, whereas estrogen maintains a disease-permissive microbiome. Studies of the microbiome in human disease are just beginning.[43]

CLINICAL MANIFESTATIONS

CLINICAL PEARLS

- Systemic lupus erythematosus (SLE) is a systemic disease with the potential to affect any organ system.
- Not all symptoms experienced by a patient with SLE are from SLE disease activity. Attribution is critical to determine before initiation of treatment. The differential diagnosis of a lupus flare mandates consideration of infection, drug toxicities, or other etiologies.
- Corticosteroid exposure should be minimized.
- In the absence of data from randomized trials, use of aggressive treatment must be balanced against associated toxicity.
- SLE patients accumulate damage from both repeated episodes of inflammatory disease and medication toxicities. Prompt recognition and appropriate treatment of disease flares should result in reduced exposure to corticosteroids and immunosuppressive agents.
- SLE patients are at increased risk of developing atherosclerotic disease, osteoporosis, malignancy, diabetes mellitus, and hypertension. It is essential to screen for and reduce modifiable risk factors.

The prevalence of the diverse clinical and laboratory features of lupus varies in published reports (Table 51.2). Both genetic and environmental factors are likely to account for much of the variability between cohorts. Characteristics of published cohorts, including inception versus long-standing lupus cohorts, community versus academic settings, socioeconomic factors, and ascertainment differences are also likely to contribute to observed differences in the prevalence of clinical manifestations. Over time, the course of lupus is characterized by flares and remissions of disease activity.

KEY CONCEPTS

- Continued heightened awareness of systemic lupus erythematosus to shorten the time between onset of symptoms and diagnosis will improve outcomes.
- Lupus is a disease characterized by recurrent flares.
- Attentive monitoring even during periods of disease remission leads to early recognition of impending flare, better control, and better prognosis.
- Lupus is a chronic disease; the importance of a therapeutic partnership between physicians and patients, emotional/social support, and patient education cannot be overemphasized.
- Advances in understanding mechanisms of disease pathogenesis correspond to advances in treatment strategies and development of therapies with improved efficacy and safety profiles.

The most common features of lupus are constitutional and include fatigue, malaise, low-grade fever, anorexia, and lymphadenopathy. These symptoms are believed to result from elevated serum levels of inflammatory cytokines and may accompany other organ system manifestations of active disease, or they may occur in isolation. Although frequent, these symptoms are nonspecific and do not aid in making the diagnosis of SLE. Symptoms of fatigue and malaise may also represent fibromyalgia, which can co-occur with SLE or confound the diagnosis.[44]

Musculoskeletal Involvement

The musculoskeletal system is the most common organ system affected in SLE; joint pain is the presenting symptom in approximately 60–70% of patients, and 85% have joint involvement after 5 years.[45]

Arthritis and Arthralgia

The pattern of joint involvement is usually symmetrical, affecting the small joints of the hands, wrists, and knees. Pain in the ankles, elbows, shoulders, or hips or monoarticular involvement is less typical. In contrast to rheumatoid arthritis, morning stiffness is typically limited to several minutes. Frequently, the subjective complaints of pain are greater than the objective findings of warmth, swelling, and erythema. Lupus arthritis is characteristically nonerosive on X-ray and nondeforming. Anticyclic citrullinated peptide antibodies occur frequently in the rare patients with erosive arthritis. Some lupus patients develop a nonerosive hand deformity with hypermobile joints secondary to tendon and ligamentous laxity (Jaccoud arthritis) (Fig. 51.3). Proliferative tenosynovitis, synovitis, small erosions not detectable on plain radiographs, and capsular swelling are features of joint and soft-tissue involvement that may be seen on MRI. The role of ultrasound and MRI in the evaluation of musculoskeletal symptoms is not established.

Joint effusions, when they occur, are usually small. The fluid is clear yellow with normal viscosity and forms a mucin clot. It is typically noninflammatory with a normal glucose level and a white blood cell (WBC) count of less than 2000 cells/mL that is predominantly lymphocytic. ANA performed on the synovial

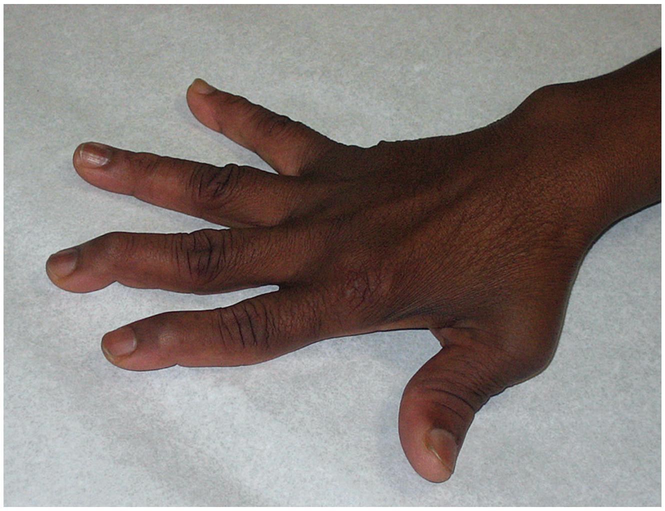

FIG 51.3 Jaccoud Arthritis in Systemic Lupus Erythematosus.

fluid may be positive, and lupus erythematosus (LE) cells may be present. Synovial fluid complement levels can be normal or depressed. Synovial histology in lupus is not specific and shows synovial hyperplasia with fibrin deposition and microvascular changes that include perivascular infiltrates in the majority of cases.

Tendinitis

Tendinitis is not usually attributed to SLE unless associated with tendon rupture. When present, it is usually located in the Achilles tendon or the tendons around the knee. Tendon ruptures are more common in males and have been associated with trauma, steroid use, long disease duration, and Jaccoud arthropathy.[46] Biopsy shows a mononuclear infiltrate with tendon degeneration and neovascularization. The diagnosis can be easily demonstrated on ultrasound or MRI.

Myositis/Myalgia

Generalized myalgia is extremely common in lupus. It frequently affects the deltoids and quadriceps and occurs during flares of active disease. Muscle disease secondary to treatment with corticosteroids, statins, and antimalarials or in association with hypothyroidism is also frequent and must be considered in the evaluation of a lupus patient with myalgia. Inflammatory muscle disease with weakness and an elevated creatine phosphokinase is less common, occurring in approximately 10% of lupus patients.[44] Electromyography can be normal or can be characteristic of the myositis observed in polymyositis or dermatomyositis. Muscle biopsy can also be normal or can show changes associated with dermatomyositis such as a perivascular or perifascicular infiltrate and immunoglobulin and complement deposition. Muscle atrophy, fiber necrosis, microtubular inclusions, and/or a mononuclear infiltrate have been documented. MRI findings are nonspecific.

Avascular Necrosis

Avascular necrosis (AVN) has been reported in up to 30% of lupus patients, is frequently asymptomatic, and is detected by MRI.[47] The most commonly affected site is the femoral head. Groin pain exacerbated with weight bearing is a common complaint. In addition to the hip, AVN can involve the knees, shoulders, and wrists. The majority of AVN is associated with previous administration of high doses of corticosteroids (>30 mg/day); associations with vitamin D deficiency, minority ethnicity, hypertension, and renal disease have also been reported. Bone biopsy in lupus patients affected by AVN does not reveal unique findings.

Mucocutaneous Manifestations

Skin

The skin is commonly affected in SLE, with a wide variety of lesions from malar erythema to severe bullous lupus and scarring discoid lesions (DLE). SLE-associated cutaneous lesions are generally categorized as acute cutaneous lupus erythematosus, subacute cutaneous lupus erythematosus (SCLE), and chronic cutaneous lupus erythematosus (CCLE). Known triggers for cutaneous SLE include ultraviolet (UV) light, infections, and drug reactions. Many lupus rashes arise in sun-exposed areas, and sun exposure can precipitate flares of systemic disease. Typically, a photosensitive rash erupts within hours of sun exposure and consists of tiny pruritic plaques and vesicles lasting several days. UV light induces DNA strand breaks in keratinocytes, resulting in apoptotic cell death and providing a rich source of autoantigen (*e.g.,* Ro52 antigen). SLE patients have increased numbers of apoptotic keratinocytes after exposure to UV light,[48] and these apoptotic cells have been identified in the basal layer of CCLE lesions. Particularly in a setting of impaired ability to clear apoptotic debris, the abundance of autoantigen provides stimuli for autoreactive T and B cells and recruitment of pDC with ensuing production of proinflammatory cytokines (IL-1, IFN-α, TNF-α, IL-6, IFN-γ). UV-oxidized DNA is resistant to cytosolic enzymatic degradation, thereby potentiating pDC expression of IFN-α. In addition to the proinflammatory cytokines, cutaneous lupus lesions demonstrate increased expression of IFN-α-inducible chemokines CXCL9, CXCL10, and CXCL11, which attract lymphocytes.[49] Transcript analysis of lesional skin in CCLE demonstrates a paucity of Tregs with increased numbers of T-helper 1 (Th1), IFN-γ producing cells. Increased NETS extruded from dying neutrophils are also seen in cutaneous lupus lesions. The DNA in NETS is resistant to degradation and may contribute to ongoing pDC activation through TLRs and IFN-α expression characteristic of cutaneous lesions.

Acute Cutaneous SLE

The malar rash typically occurs across the cheeks and nose but can include the forehead and chin, sparing the nasolabial folds (unlike seborrheic dermatitis) (Fig. 51.4). It usually begins as small discrete erythematous macules or papules that coalesce, is frequently associated with sun exposure, and heals without scarring. Some patients additionally have facial swelling. The differential diagnosis includes acne rosacea, seborrheic dermatitis, erysipelas, dermatomyositis, and contact dermatitis. Microscopical analysis reveals a sparse inflammatory lymphocytic dermatitis with occasional histiocytes engulfing nuclear debris resembling LE cells found close to the dermoepidermal junction. Immunofluorescent staining for complement components and immunoglobulin at the dermoepidermal junction is positive in 70–80% of patients.

Subacute Cutaneous SLE

SCLE is characterized by recurrent, nonscarring skin lesions. This distinctive rash consists of erythematous papules and plaques, with or without adherent pityriasiform scale, that erupt on the

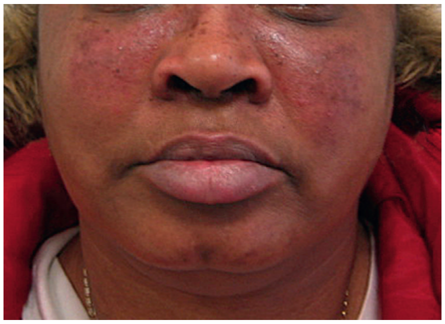

FIG 51.4 Malar Rash in a Systemic Lupus Erythematosus Patient.

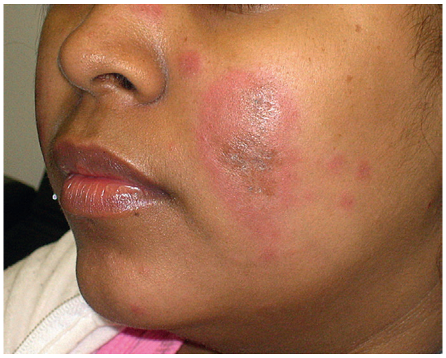

FIG 51.5 Discoid Lesion in Systemic Lupus Erythematosus.

extremities and trunk, usually sparing the head and neck. These lesions may assume an annular polycyclic form with central pallor and tiny vesicles at the active margins and can be mistaken for erythema multiforme. The differential diagnosis also includes psoriasis, polymorphic light eruption, and tinea corporis. SCLE is exacerbated by UV light and a growing list of medications, including thiazides and calcium channel blockers. Biopsy reveals a lymphocytic dermatitis confined to the superficial and mid dermis, frequently with associated dermal edema, mucinosis, and degenerating keratinocytes. Both TNF-α and IL-6 have been demonstrated in active SCLE lesions. SCLE is most commonly seen in Caucasian populations. Genetic analyses have revealed associations with HLA-A1, HLA-B8, and HLA-DR3 haplotypes as well as with deficiencies of C2, C4, and C1q. From 60–90% of SCLE patients have circulating anti-Ro antibodies; however, they are also deposited in nonlesional skin.

Chronic Cutaneous SLE

DLE are usually localized to the head and neck in photo-exposed areas, with a predilection for the ears and periorbital areas (Fig. 51.5). The lesions vary in size and result in scar tissue with significant disfigurement. Early lesions appear as erythematous plaques with or without follicular hyperkeratosis, plugging, and scale and progress to scarring annular lesions with an erythematous, indurated border, adherent scale, and a central area with atrophy and telangiectasias. There are no autoantibody associations with DLE, and only 5% of patients with DLE develop systemic lupus. High-titer ANA, Raynaud phenomenon, and the presence of arthralgias may identify patients at risk for systemic evolution. Histopathology characteristically reveals a lymphocytic interface dermatitis with CD4 lymphocytes and pDCs involving follicles and epidermis. There is vacuolar degeneration of the basal layer of epidermal keratinocytes and prominent keratotic follicular plugging. Dermal mucin deposition is also present, and there is usually dense granular deposition of immunoglobulin (predominantly IgG) and C3 at the dermal–epidermal junction. Patients with C2, C4, and C1q deficiencies may be predisposed to DLE, and promoter region polymorphisms leading to high IL-10 and low TNF-α are risk factors for DLE.

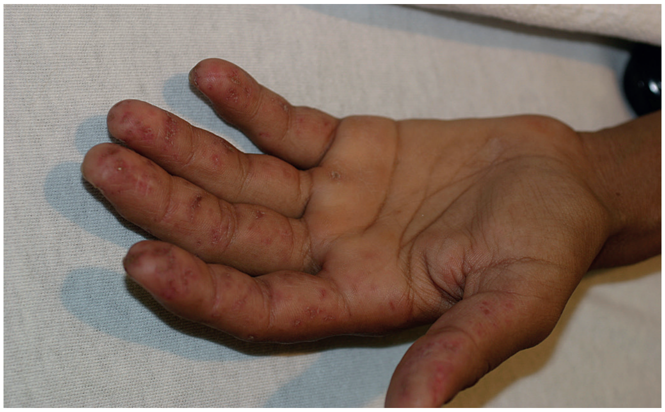

FIG 51.6 Cutaneous Vasculitis Affecting the Hands in a Patient With Active Systemic Lupus Erythematosus.

Lupus profundus typically presents as firm, tender, deep subcutaneous nodules that may atrophy over time. Overlaying epidermal changes include DLE, ulcerations, and dystrophic calcification. Biopsy reveals a lobular panniculitis with patchy lymphoplasmacytic infiltrate in subcutaneous fat lobules. Panniculitis occurs in 10–20% of patients and must be differentiated from a subcutaneous T-cell lymphoma, erythema nodosum, pancreatic panniculitis, and morphea.

Nonspecific skin lesions reported in SLE are typically seen during disease flares and are associated with greater disease severity. These lesions include, but are not limited to, entities such as cutaneous vasculitis (Fig. 51.6), urticaria, Raynaud phenomenon, livedo reticularis, alopecia, sclerodactyly, calcinosis cutis, atrophie blanche, bullous lesions, erythema multiforme, lupus tumidus, and leg ulcers. Nonspecific cutaneous lesions such as cutaneous vasculitis or ulcers are associated with a more aggressive disease course than most of the SLE-specific lesions.

The lupus band test (LBT) refers to the deposition of immunoglobulin (IgG, IgM, and/or IgA) and/or C3 along the dermoepidermal junction. Approximately 25% of normal individuals display weak IgM staining at the dermoepidermal junction, whereas 70–80% of SLE patients have a positive LBT in sun-exposed, nonlesional skin. Half of SLE patients have a positive LBT in non-sun-exposed, nonlesional skin. It is unclear whether the LBT is a consequence of circulating ANA targeting denatured DNA from UV light–damaged keratinocytes, or a result of immune complex deposition or antibasement membrane antibodies. The test may be useful diagnostically and prognostically, as it correlates with increased systemic disease severity.

Hair and Nail

Hair involvement in SLE includes scarring alopecia resulting in permanent hair loss, induced by DLE. This can be differentiated from other common forms of scarring alopecia by immunofluorescent studies. Patchy or diffuse nonscarring alopecia is frequently associated with disease activity. Histologically, there is a peribulbar lymphocytic infiltrate surrounding shrunken anagen hair bulbs similar to findings in alopecia areata. Nonscarring alopecia resolves with complete hair regrowth with control of disease activity.

A wide spectrum of nail abnormalities, including pitting, ridging, onycholysis, and dyschromia with blue or black hyperpigmentation, are reported in up to 30% of SLE patients, but none are lupus-specific. Nail fold erythema with ragged cuticles and splinter hemorrhages resembling the changes of dermatomyositis are common.

Oral Lesions

The spectrum of oral lesions reported in SLE includes cheilitis, ulcerations, erythematous patches, lichen planus–type plaques on the buccal mucosa and palate, and DLE.[50] Most oral lesions are asymptomatic and must be looked for on examination. Positive immunofluorescent staining on biopsy may be useful to differentiate DLE from lichen planus–like lesions and leukoplakia. Lupus mucosal ulcerations demonstrate an interface mucositis and not leukocytoclastic vasculitis.

Gastrointestinal Manifestations

GI symptoms occur commonly in SLE with reported incidences of 15–75%; attribution is critical, as at least half are attributable to side effects of medications and to infectious complications.[51]

Esophagus

The prevalence of esophageal involvement varies. Many reviews citing a high incidence of dysphagia and odynophagia predate the advent of proton pump inhibitors and H_2 blockers, and the relationship of medication use to symptoms is not clear. Dysphagia and heartburn are reported in 1–50% of patients, although esophageal dysmotility is observed in up to 72%. An inflammatory process involving esophageal muscle or vasculitic damage to the Auerbach plexus is thought to contribute to the esophageal dysmotility. Ulceration is rarely seen outside the context of infections such as invasive candidiasis, herpes simplex, or cytomegalovirus. SLE patients with a secondary Sjögren syndrome may have salivary gland dysfunction, resulting in decreased saliva contributing to dysphagia.

Abdominal Pain/Vasculitis

Acute abdominal pain is common in SLE with reported incidences as high as 40%. The differential diagnosis includes intestinal vasculitis (45.5%), pancreatitis (10.8%), hepatobiliary disease (18.8%), and intestinal pseudoobstruction (IPO) (3.3%).[52] The most catastrophic and potentially fatal GI disturbances are related to ischemia of the small and large intestines resulting from medium- and small-vessel vasculitis or thrombotic complications of antiphospholipid (APL) antibodies. Approximately half of SLE patients with acute abdominal pain will have intestinal ischemia; associated mortality is high, so early consideration and intervention is critical. Intestinal vasculitis is frequently associated with active disease elsewhere and increased SLE Disease Activity Index (SLEDAI) scores, whereas SLE patients with inactive disease and acute abdominal pain will have different intraabdominal pathology unrelated to SLE. The clinical presentation may be acute, severe abdominal pain or an insidious, stuttering course with nausea, vomiting, bloating, diarrhea, postprandial fullness, anorexia, and weight loss. Mesenteric vasculitis preferentially affects the superior mesenteric artery, involving the small intestine more commonly than the large bowel. Vasculitis can also occur in the esophagus, stomach, peritoneum, rectum, gallbladder, pancreas, and liver. Computed tomography (CT) and/or magnetic resonance with or without angiography are the preferred imaging tests for evaluation of abdominal pathology; the radiographic signs of intestinal ischemia do not differ based on pathogenesis.

In cases with an insidious clinical course, endoscopy and colonoscopy may provide evidence of ischemia demonstrating ulcerating or heaped-up lesions with overt vasculitis on biopsy. The lesions are segmental and focal. Histologically, there is a small-vessel arteritis and venulitis with neutrophilic, lymphocytic, and macrophage infiltrates and fibrinoid necrosis of the vessel walls, associated thrombosis, and mononuclear infiltrate in the lamina propria. There may be immunoglobulin, C3, and fibrin deposition in the adventitia and media.

Timely treatment with high-dose intravenous corticosteroids (1–2 mg/kg per day) usually results in a favorable outcome and avoidance of serious complications such as bowel necrosis and perforation. To date there are no randomized trials of immunosuppressive agents for the treatment of intestinal vasculitis.

Intestinal Pseudoobstruction

Though rare, SLE-associated intestinal pseudoobstruction (SLE-IPO) may be the initial manifestation of SLE.[51,53] Clinical symptoms (abdominal pain and distension with diminished or absent peristalsis) and radiographic findings of SLE-IPO mimic those of mechanical obstruction. Distinguishing features of SLE-IPO include concomitant active SLE in other organ systems and associations with hematological cytopenias, hypocomplementemia, and serositis. Findings of coexisting ureterohydronephrosis and hepatobiliary dilatation in the absence of obstructing lesions suggest underlying smooth muscle dysmotility. Poor prognosis is associated with older age at SLE diagnosis, GI symptoms as the initial SLE manifestation, longer disease duration, and delayed diagnosis of IPO.

Peritonitis

Inflammation of serosal membranes is well described in SLE; despite evidence of peritoneal inflammation in 63% of autopsy studies, symptomatic pericarditis and pleuritis occur far more commonly than peritonitis. Acute peritonitis may be attributed to peritoneal vasculitis or ischemia and presents with abdominal pain (see above). The finding of ascitic fluid by CT scan or ultrasound mandates an evaluation of the fluid to exclude infection and malignancy. Rarely, ascites may be attributable to hepatic or portal vein thrombosis. Chronic peritonitis characterized by large amounts of painless ascites attributable to SLE and not to heart failure, constrictive pericarditis, or severe hypoalbuminemia due to nephrotic syndrome, liver disease, or a protein-losing enteropathy (PLE) is rare. In lupus peritonitis, the ascitic fluid is generally exudative with a predominance of lymphocytes; LE cells, autoantibodies, and low complement levels are frequent. On biopsy, the peritoneum is usually edematous; it is sometimes hemorrhagic with lymphocytic perivascular infiltrates.

Pancreatitis

Pancreatitis attributable to SLE is rare, occurring in 8–11% of patients with abdominal pain and having an annual reported incidence ≤1/1000. Although both corticosteroids and azathioprine can trigger pancreatitis, 34% of reported cases are not on these medications at the onset of pancreatitis, and most patients respond to steroid therapy. The clinical presentation and diagnosis of pancreatitis is similar in patients with and without SLE. Specific findings in SLE include leukopenia, thrombocytopenia, and anemia. Inflammation and necrosis are common on biopsy; there is a single report of pancreatic vasculitis. Mortality rates are reported from 18–27%; poor outcome is associated with increased systemic SLE activity (particularly, low complement and thrombocytopenia).

Liver

The term "lupoid hepatitis" was coined in the 1950s to describe cases of young women with chronic active hepatitis characterized by a lymphoplasmacytic infiltrate on biopsy, hypergammaglobulinemia, and a positive LE cell test in the blood. With the development of ANA testing, it became apparent that "lupoid" and "chronic active hepatitis" were indistinguishable in terms of clinical presentation, pathology, and response to treatment, and the term "autoimmune hepatitis" (AIH; Chapter 76) was endorsed in 1993.[54] Importantly, only 10% of AIH meet criteria for SLE, and 2.4–4.7% of SLE patients have noninfectious hepatitis attributed to SLE.[51] Analysis of SLE liver pathology from 52 autopsies in Japan revealed a variety of findings, including congestion (40/52), fatty liver (38/52), arteritis (11/52), cholestasis (9/52), and a few cases each of chronic persistent hepatitis, nodular regenerative hyperplasia, hemangioma, and cholangiolitis. Cirrhosis is an extremely rare complication of liver involvement in SLE. The distinction between subclinical liver inflammation related to SLE (lupus hepatitis [LH]) and AIH is important because therapy and prognosis are different. Whereas LH is associated with mild enzyme abnormalities, AIH is a progressive disease frequently leading to hepatic failure. Both conditions share a predilection for young women, and both demonstrate features of autoimmunity, including hypergammaglobulinemia, arthralgias, and serum autoantibodies. Histologically, biopsies of LH reveal lobular and periportal lymphocytic infiltrates, in contrast to the periportal and piecemeal necrosis with dense lymphocytic infiltrates seen in AIH with progression to panlobular or multilobular necrosis and cirrhosis. Serologically, antiribosomal P antibodies have been associated with liver disease in LH, whereas AIH is associated with antibodies to liver and kidney microsomes. Antismooth-muscle antibodies are observed in 60–80% of patients with AIH, compared with 30% of patients with LH. Although both have a favorable response to steroids, AIH usually requires additional immunosuppressive agents.[54]

Distinguishing LH from hepatitis C (HCV) can be difficult. Up to 30% of patients chronically infected with HCV have low titers of ANA and other autoantibodies (anti-DNA, anticardiolipin antibodies, and rheumatoid factor). They can also have cryoglobulins and associated cryoglobulinemic vasculitis. It is necessary to confirm a positive enzyme-linked immunosorbent assay (ELISA) for HCV with polymerase chain reaction (PCR) in patients presenting with arthritis, cutaneous vasculitis, and a positive ANA, as SLE patients may have false-positive serological tests for HCV.

Protein-Losing Enteropathy (PLE)

Profound hypoalbuminemia in the absence of severe nephrotic syndrome, liver disease, or constrictive pericarditis should trigger concern for PLE. Clinically significant PLE is uncommon in SLE, with reported prevalence rates of 1–8%; it can present individually or in the context of severe disease activity with other organ involvement. The diagnosis is confirmed with an increased α_1-antitrypsin level in a 24-hour stool collection or with the presence of IV-administered labeled human albumin in the stool. A recent review of 112 cases reported an Asian predominance (65%) and clinical features of edema (805), ascites (38%), pleural effusion (38%), pericardial effusion (21%), and hypocomplementemia (79%). Approximately half the patients experienced diarrhea; intestinal histology revealed a range of findings, including lymphangiectasis, edematous villi, inflammatory infiltrate, vasculitis, and mucosal atrophy. Biopsy results suggest a role of TNF-α, IFN-γ, and IL-6 in the increased vascular and enterocyte permeability in PLE.

Pulmonary Involvement

Lupus affects the lungs in diverse ways involving the pleura, lung parenchyma, and blood vessels. The most frequent and important complicating feature is infection.

Pleuritis

Pleuritis is the most common pulmonary manifestation of SLE, reported in 40–56% of patients.[55] Pleural involvement in up to 93% of lupus patients at autopsy suggests that much pleuritis may be asymptomatic. Clinically, patients note typical pleuritic pain. On physical examination, the most frequent abnormality is tachypnea; a pleural friction rub is present in some cases, and pleural effusions occur in more severe cases. Pleural fluid is usually exudative with normal glucose and pH and elevated protein levels. The leukocyte count can range from several hundred to 20 000 cells/μL; both a lymphocytic and neutrophilic predominance are reported. When performed, immunological testing on pleural fluid may show reduced complement levels and the presence of ANA, anti-DNA antibodies, and LE cells. Although these tests are commonly obtained, these results are neither sensitive nor specific to diagnose lupus pleuritis.

Lupus Pneumonitis

Lupus pneumonitis occurs in up to 10% of patients. Patients present with dyspnea, cough, mild pleuritic chest pain, and fever. Pulmonary infiltrates are present on plain radiograph or CT. This presentation must be distinguished from an infectious etiology. Histological examination of affected lung tissue shows alveolar edema and hemorrhage with hyaline membrane formation; immunofluorescent staining reveals immune complex deposition.

Pulmonary Hemorrhage

Pulmonary hemorrhage is a rare but potentially fatal complication of SLE. Symptoms include shortness of breath and hemoptysis accompanied by a fall in hemoglobin, usually occurring in the context of multiorgan involvement from SLE. Imaging may show patchy infiltrates. Pulmonary function testing is marked by an increased diffusion capacity (DL_{CO}) secondary to the presence of alveolar blood, whereas arterial O_2 saturation is decreased. Histopathology shows bland intraalveolar hemorrhage and hemosiderin-laden macrophages, although microangiitis with an inflammatory infiltrate and necrosis of the alveolar septa can occur. As hemorrhage into the lung may be secondary to thrombotic thrombocytopenia, infections, or pulmonary hypertension, demonstration of an inflammatory process in the pulmonary vessels or tissue is helpful to establish a diagnosis of primary pulmonary hemorrhage.

Chronic Diffuse Interstitial Lung Disease

Chronic diffuse interstitial lung disease is a relatively uncommon manifestation of SLE and is occasionally associated with anti-Ro antibodies. It usually has a progressive course with a chronic nonproductive cough, dyspnea, and pleuritic chest pains. Physical examination is frequently remarkable for basilar rales with diminished diaphragmatic movement. Pulmonary function tests demonstrate a restrictive pattern with decreased diffusion capacity; oxygen saturation is decreased. Imaging often shows interstitial fibrosis that is more prominent at the lung bases. High-resolution CT (HRCT) may also help determine the extent of treatable disease, *i.e.,* fibrosis (honeycombing) versus inflammation (ground glass). However, the most reliable method to assess the extent of pulmonary inflammation in comparison to fibrotic damage is histological examination. Evaluation of bronchial alveolar lavage fluid helps to exclude infection.

Pulmonary Hypertension

Pulmonary hypertension unrelated to chronic pulmonary emboli or interstitial lung disease occurs in SLE. Severe cases are rare; the recent recognition of milder cases may be partially attributed to increased awareness and findings of elevated pulmonary artery pressures on echocardiograms obtained for evaluation of shortness of breath. Patients typically present with progressive dyspnea occurring in the absence of infiltrates on chest radiographs or significant hypoxemia. Chest pain and a chronic nonproductive cough are also frequently present. Pulmonary function testing reveals a reduced DL_{CO}. Elevated pulmonary artery pressure is confirmed with cardiac angiogram. Biopsy or autopsy specimens of the lung reveal "plexiform" lesions that resemble those seen in primary pulmonary hypertension.

Shrinking-Lung Syndrome

The shrinking-lung syndrome refers to the rare findings of shortness of breath occurring in the absence of pleuritis or interstitial lung disease plus a chest X-ray showing elevated hemidiaphragms. Pulmonary function testing shows a restrictive pattern with loss of lung volume. It had been generally accepted that this syndrome results from diaphragmatic weakness (from a myopathic process) or chest wall restriction; however, more recent studies suggest that pleuritis may play a causative role. There is no definitive therapy, although immunosuppressive therapy with cytotoxic agents usually results in an improvement of lung function and respiratory symptoms.

Cardiac Involvement

There are a number of ways in which lupus affects the cardiovascular system; targets include the myocardium, valves, pericardium, and vessels.

Myocardium

Myocardial dysfunction in SLE is likely to be secondary to factors other than lupus, such as hypertension, medications, or coronary artery disease (CAD). However, a cardiomyopathy resulting from immune-mediated myocardial inflammation does occur, either in isolation or concomitant with myositis or other manifestations of systemic disease. Inflammatory myocarditis is often associated with anti-RNP antibodies. Histopathology typically shows a mononuclear, inflammatory cell infiltrate. Perivascular or myocardial wall deposits of immune complexes and complement also occur. Myocardial biopsy is critical for diagnosis as well as for determining the extent of active inflammatory disease and fibrosis. Symptoms and signs of myocarditis include unexplained tachycardia, an abnormal electrocardiogram (with ST- and T-wave abnormalities), cardiomegaly, and heart failure. Echocardiography may show systolic and diastolic ventricular dysfunction. Myocardial involvement without overt clinical signs occurs commonly and may be documented using Doppler echocardiography. A noninflammatory cardiomyopathy may be seen in association with high-dose cyclophosphamide and, although rarely, with hydroxychloroquine.

Valvular Heart Disease

Valvular abnormalities, with thickening, regurgitation, or verrucous vegetations, occur commonly in SLE (50–60%) and are documented by transesophageal echocardiography.[56] The characteristic Libman–Sacks lesion, nonbacterial verrucous vegetations, is observed at autopsy in 15–60% of patients. Mitral, aortic, and tricuspid valves are most frequently involved. Clinically these lesions are usually asymptomatic, and hemodynamic compromise, rupture of the chordae tendineae, or infection are rare events. On histological examination, mononuclear cells, hematoxylin bodies, fibrin and platelet thrombi, and immune complexes are present. Antiphospholipid antibodies can be associated with the development of valvular heart disease, although their pathogenic role remains unproven.

Pericarditis

Pericardial inflammation in SLE is frequent. Although asymptomatic pericarditis occurs in more than 50% of patients, clinically apparent pericarditis occurs in only 25%, and cardiac tamponade and constrictive pericarditis are infrequent. Pericardial fluid and thickening are easily detected by echocardiography; cardiac silhouette enlargement on plain films is seen in the presence of large effusions. There are no unique signs and symptoms of pericarditis in lupus patients. The histological findings of acute pericarditis in lupus are inflammation with a mononuclear cell infiltrate accompanied by immunoglobulin and complement deposition. Results of pericardial fluid analysis are neither sensitive nor specific; the fluid is usually an exudate with elevated protein concentrations, normal or low glucose levels, and an elevated WBC count that is primarily neutrophilic. Complement levels in the fluid are low, and autoantibodies (ANA, dsDNA) and LE cells have been reported.

Coronary Artery Disease

Myocardial infarction, angina, and sudden death resulting from CAD are well described in SLE. Estimates of the prevalence of CAD vary widely depending on the methodology used for ascertainment; however, the risk of myocardial infarction has been estimated to be 50-fold greater in young women with lupus than in normal age-matched controls.[57] Cardiac events occur both late in the course of SLE as well as early, and may even predate the SLE diagnosis. Coronary artery vasculitis is a potential cause of CAD but is exceedingly rare, and bland atherosclerotic plaque is typically described in surgical and postmortem specimens. Traditional risk factors for CAD, such as hypertension, diabetes, and hyperlipidemia, are enriched in lupus patients, and an increased prevalence of the metabolic syndrome likely contributes additional risk. Lupus-related risk factors include duration of SLE, duration of corticosteroid use, renal disease, and absence of use of hydroxychloroquine. The potential contributing influence of antibodies to phospholipids or disease activity continues to be explored. There is a growing body of evidence supporting a risk conferred by inflammation *per se.* The atherosclerotic plaque is infiltrated by activated macrophages and T cells that produce proinflammatory cytokines. Inflammation may accelerate both the formation and the rupture of atherosclerotic plaque. In SLE, the pathology of acute events seems to focus on unstable plaque. If endothelial dysfunction and vascular injury are the events triggering atherosclerosis, there are multiple potentially responsible processes in lupus; these include, but are not limited to, autoantibodies directed to endothelial cells, immune complexes, and enhanced cleavage of membrane endothelial protein C receptor.[58]

Renal Involvement

Lupus nephritis is a common manifestation of disease with significant impact on morbidity and mortality (Chapter 68). The prevalence of nephritis ranges from 50–75% overall, with increased prevalence of proliferative nephritis and more aggressive disease in African Americans and Hispanics compared with Caucasians. Low socioeconomic status, independent of ethnicity, is predictive of poor prognosis, and pediatric lupus and male lupus are both associated with a greater incidence of, and more aggressive, nephritis. Onset of nephritis frequently occurs within 2 years after diagnosis, but it may occur at any time, so monitoring for potential renal activity is an ongoing obligation. Clinically, patients are asymptomatic unless they are nephrotic or have developed end-stage renal disease. Detection typically relies on examination of the urine, although a rising creatinine or hypertension may herald renal involvement. The presence of proteinuria on urinalysis, hematuria (>5 red blood cells (RBCs)/high-power field), or pyuria (>5 WBCs/high-power field) in the absence of other etiologies should prompt an evaluation for nephritis. A 24-hour urine collection remains the most accurate measurement of urinary protein loss; however, the protein/creatinine ratio in a spot urine is accepted and more commonly used when monitoring patients. Monitoring serum creatinine as a surrogate for the glomerular filtration rate is standard; however, creatinine is an insensitive marker of lupus renal disease and should be used in conjunction with other assays. Renal activity is usually preceded or accompanied by serological activity. Antibodies to dsDNA are almost always elevated or rising, whereas measurements of serum complement (C3, C4, or CH_{50}) are usually low or dropping.

Histological findings of the kidney in lupus nephritis can be defined using the classification proposed by the International Society of Nephrology/Renal Pathology Society (ISN/RPS).[59] In general, membranous nephritis (class V) presents with a bland urinary sediment (*i.e.,* no RBCs, WBCs, or casts), nephrotic-range proteinuria, a normal to mildly elevated creatinine, a normal blood pressure, and normal serologies. Patients with mesangial disease (class II) present with a bland or minimally active sediment, low-grade proteinuria (less than 500 mg/24 hours), and a normal serological profile. Class III (focal) and class IV (diffuse) proliferative nephritis are characterized by active urinary sediment, proteinuria (>500 mg/24 hours), active serologies, and, frequently, hypertension and elevated serum creatinine. Class III is defined as ≤50% glomerular involvement, and class IV is defined as >50%. The extent of proteinuria, urinary sediment activity, serological abnormalities, and creatinine elevation is often less in class III than in class IV renal disease. Most cases of class II nephritis do not require initiation of cytotoxic therapy, and progression to end-stage kidney disease is rare. The prognosis of class III disease is dependent on the degree of activity; patients with 40–50% of glomerular involvement have a prognosis similar to that of patients with class IV disease. In addition to the number of involved glomeruli, renal biopsy assessment includes measures of activity (proliferative response) and chronicity (sclerotic response). Therapeutic intervention in class III or IV disease usually requires cytotoxic therapy in addition to high-dose corticosteroids, provided the chronicity index is not too high, indicating irreversible damage. Even with potent immunosuppressant therapy such as cyclophosphamide or mycophenolate mofetil, a complete response is induced in only approximately 20%, with a partial response in about 80% of patients. Moreover, repeat histopathological studies of kidney biopsies in patients achieving a complete clinical response show ongoing renal inflammation in almost half. Relapses and flares of renal disease are not infrequent, particularly when tapering corticosteroids or discontinuing immunosuppressive treatment. Potential therapies that maintain podocyte integrity or prevent activation of renal endothelial cells as well as agents directed against inflammatory cytokines, B cells, or T cells may offer therapeutic advantage and improved renal outcome.[60]

Hematological

Hemocytopenias occur frequently in SLE, and prevalence varies among lupus cohorts (Fig. 51.7). Evaluation for medication effects is essential before attributing a cytopenia to an immune-mediated mechanism.

Anemia

Antibody-mediated peripheral destruction of RBCs, autoimmune hemolytic anemia (AHA), occurs in 5–14% of SLE patients.[61] In the multiethnic Latin American GLADEL cohort, AHA was an independent predictor of damage accrual and decreased survival and was associated with disease activity.[62] The antierythrocyte antibody is usually an opsonizing IgG. The specificities of the antierythrocyte antibodies in SLE have not been clearly defined; the only nonrhesus-specific antigen reported in SLE is the membrane band 3 anion transporter protein. The presence of AHA is readily diagnosed by a positive Coombs test, elevated lactate dehydrogenase and total bilirubin, low serum haptoglobin, and the presence of spherocytes on the peripheral smear. AHA in SLE has also been associated with APL antibodies, which may reflect cross-reactivity with erythrocyte membrane antigens.[63]

Anemia of chronic disease is the most common cause of anemia in SLE; however, if the hemoglobin is <10 g/dL, another cause of anemia should be considered. The inhibitory effects of proinflammatory cytokines on erythrocyte production can be compounded by increased hepcidin levels and an inadequate erythropoietin response. Low erythropoietin levels in SLE may be attributable to renal disease as well as antierythropoietin antibodies. Although hemophagocytosis of hematopoietic cells is frequently noted on bone marrow biopsies, the hemophagocytic syndrome characterized by spiking fevers, tender hepatosplenomegaly, anemia, leukopenia, and markedly elevated serum ferritin is rare.

Lupus is also associated with a thrombotic microangiopathic hemolytic anemia with schistocytes, helmet cells, and triangular fragments of RBCs. The clinical constellation of high fever, renal insufficiency, neurological symptoms, and thrombocytopenia is characteristic of thrombotic thrombocytopenic purpura (TTP). Coexistent TTP and SLE is a rare and frequently fatal phenomenon that has been associated with antibodies to ADAMTS 13 (von Willebrand factor cleaving protease) in 16% of SLE-associated TTP and APL antibodies.

Leukopenia

Leukopenia, either neutropenia or lymphopenia, occurs in 20–40% of patients.[64] Lymphopenia (lymphocytes <1500/mm^3) has a reported prevalence of 15–80%, whereas severe lymphopenia (<500/mm^3) occurs in 4–10% of SLE patients. The prevalence of neutropenia, variably defined in the literature as <1800 to <2500/mm^3, is 20–40%, whereas severe neutropenia (<1000/mm^3) is rare (1–4% prevalence). Both neutropenia and lymphopenia can reflect disease activity; however, associations with infection remain controversial. Carli et al. found that associations between leukopenia and major infection lost significance in half of published studies after controlling for confounding factors.[64]

Autoantibodies are the pathogenic mechanism generally implicated in the leukopenias. Antineutrophil antibodies directed against membrane components of mature and progenitor cells, resulting in decreased phagocytosis and accelerated apoptosis, are implicated, as are antibodies against granulocyte–colony-stimulating factor (G-CSF) and hyposensitivity of myeloid cells to G-CSF. Binding of TNF-related apoptosis-inducing ligand (TRAIL) to TRAIL receptors on neutrophils accelerates neutrophil apoptosis.[65] One of four known TRAIL receptors is unable to transduce the death signal and functions as a decoy receptor; this receptor is reduced in SLE patients with neutropenia and is upregulated by steroid therapy. Lymphocytotoxic antibodies, particularly to CD4 T cells, increased apoptosis related to Fas and Fas ligand upregulation, and increased serum IL-10 levels have all been implicated in the pathogenesis of lymphopenia. B cells expressing the 9G4 idiotype found on V_H 4.34 heavy chains may be responsible for production of antilymphocyte antibodies.

Treatment of leukopenia is guided by the clinical scenario, and exclusion of drug effects, malignancy, or myelofibrosis is required before attribution to SLE. In the absence of recurrent infection, leukopenia in SLE rarely warrants treatment, as increased steroids can also contribute to the risk of infection. Severe leukopenia has been treated with G-CSF; however, although it is rapidly effective, G-CSF has also been associated with disease flare in 30% of cases.

Thrombocytopenia

Low platelet counts are seen in approximately 25% of patients, although severe thrombocytopenia is reported in fewer than 10%. Immune-mediated consumption is the most frequent cause, but in rare instances thrombocytopenia occurs as a manifestation of microangiopathic hemolytic anemia, TTP, disseminated intravascular coagulation (DIC), or as part of the hemophagocytic syndrome, all of which are associated with high mortality and morbidity. A pathogenic role for antibodies against platelet membrane glycoproteins (IIb/IIIa antigen) is well established.[66] Other possible mechanisms include antibodies to the thrombopoietin receptor (TPOR), and APL and anti-CD40-ligand antibodies that bind to platelets, resulting in platelet sequestration.

Central and Peripheral Nervous System

Neurological and psychiatric manifestations of SLE are diverse and frequently occur irrespective of systemic disease activity. Neuropsychiatric symptoms can be focal or diffuse, peripheral or central, isolated or complex, and difficulties with assessment and attribution of individual symptoms have hindered progress in understanding mechanisms for neuropsychiatric disease attributable to SLE (NPSLE).

NPSLE Nomenclature

In 1999 a consensus committee established by the ACR developed reporting standards, case definitions, and recommendations for laboratory and imaging studies for 19 neurological, psychiatric, and cognitive syndromes. Diagnosis of NPSLE requires the exclusion of infections, metabolic disturbances, bleeding disorders, malignancy, and medication toxicities. Using this nomenclature, NPSLE is common overall, with a prevalence of 57–95%. Individually, headache, mood disorders, cerebrovascular events, cognitive dysfunction, and seizures are frequent; polyneuropathy, demyelinating disease, mononeuritis, myasthenia gravis, chorea, cranial neuropathy, myelopathy, and Guillain–Barré syndrome are uncommon. NPSLE can be further subdivided into syndromes occurring in the anatomically distinct central (CNS NPSLE) and peripheral (PNS NPSLE) nervous systems.

Manifestations of CNS NPSLE include focal neurological syndromes (stroke, seizures, aseptic meningitis, movement disorder, myelopathy, demyelinating syndrome) and diffuse psychiatric/neuropsychological syndromes (mood and anxiety disorders, psychosis, acute confusional state, cognitive dysfunction, headaches). PNS NPSLE syndromes include cranial neuropathy, polyneuropathy, mononeuropathy, myasthenia gravis, Guillain–Barre syndrome, plexopathy, and autonomic neuropathy (Fig. 51.7).

NPSLE Pathogenesis

Many of the focal CNS NPSLE syndromes occur in association with APL antibodies and thrombotic events or, more rarely, with small-vessel vasculitis leading to intraluminal thrombosis. In contrast, proposed mechanisms for the diffuse CNS NPSLE syndromes involve autoantibody-mediated neurotoxicity and complicated neuroimmune interactions, resulting in increased CNS expression of proinflammatory cytokines with deleterious effects on neuronal and microglial cell function and adult neurogenesis.[67,68] Proposed mechanisms for diffuse CNS NPSLE rely in large part on disruption of the blood–brain barrier (BBB)—a dynamic interface between the brain and circulating hormones and inflammatory molecules. Evidence for BBB disruption in SLE is supported by reports of an elevated albumin concentration gradient between cerebrospinal fluid (CSF) and plasma, an elevated IgG index, and elevated serum levels of proteins whose origins are exclusive to the brain parenchyma, such as S100B. Proposed mechanisms for BBB disruption in SLE include brain endothelial cell disruption mediated by inflammatory cytokines, chemokines, complement C5a, antiendothelial cell antibodies, anti-NMDAR antibodies, and TWEAK (TNF-like weak inducer of apoptosis).[69–71]

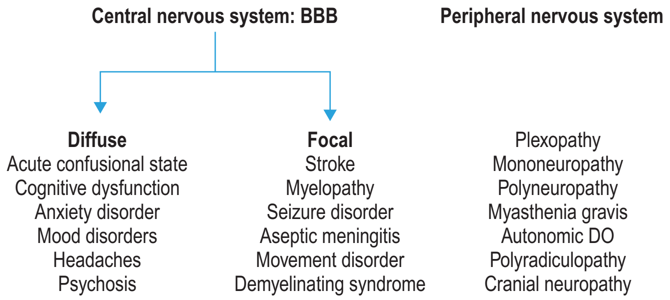

FIG 51.7 Neuropsychiatric Syndromes in Systemic Lupus Erythematosus.

This distinction between focal and diffuse CNS NPSLE and potential mechanisms is essential for the development of treatment strategies. Thrombotic events associated with APL antibodies are treated with anticoagulation, whereas high-dose corticosteroids and immunosuppression in combination with neuroleptic and antiseizure medications are generally required for treatment of diffuse CNS events. Because there is no intervening BBB, peripheral nerves are more accessible to circulating complement, autoantibodies, and inflammatory molecules, and vasculitis of epineural arteries is a common finding in PNS NPSLE. Treatment consists of corticosteroids and immunosuppression or intravenous immunoglobulin (IVIG).

NPSLE Assessment and Attribution

The diagnosis of diffuse CNS NPSLE is frequently difficult, and the clinical evaluation of a patient with presumed CNS NPSLE mandates an exhaustive search for other potential causes. CSF examination is useful for excluding infection or malignant cells. Although CSF in NPSLE can be characterized by a lymphocytosis and increased immunoglobulin with elevated total protein, IgG index, and oligoclonal bands, these abnormalities are not consistently present. Numerous autoantibodies (ANA, anti-dsDNA, anticardiolipin, antiribosomal P, anti–N-methyl D-aspartate receptor [NMDAR], antineuronal, anti-RNP, anti-Sm) and various cytokines have been identified in the CSF of patients with SLE; however, none is specific for active NPSLE or individual CNS NPSLE syndromes, and routine testing is not recommended. MRI is extremely sensitive for detection of structural lesions and new ischemic lesions associated with focal CNS NPSLE, but it is frequently not helpful in diagnosing active diffuse CNS NPSLE, as MRI studies may be normal in patients with psychiatric syndromes and global CNS dysfunction.[72] Imaging studies of neuronal function, positron emission tomography (PET), and single-photon emission computed tomography (SPECT) scans measuring cerebral glucose uptake and blood flow, respectively, magnetic resonance spectroscopy, and functional MRI (fMRI) correlate to a limited extent with diffuse CNS NPSLE. These scans must be interpreted carefully because atrophy with neuronal cell loss leads to changes in metabolism and blood flow. Cerebral angiograms can be helpful if a diagnosis of cerebral vasculitis is considered; however, CNS vasculitis is rare, with true vasculitis in only 5–8% of autopsies. More commonly, a bland vasculopathy with degenerative and proliferative changes in small vessels, perivascular infiltrates, microinfarcts, and microhemorrhages is present.

There are no serological tests specific for CNS NPSLE. Serological evidence of disease activity (elevated anti-DNA antibodies and low complement) may help to diagnose CNS NPSLE, particularly if combined with other clinical signs of active disease. However, CNS NPSLE can also flare in the absence of serological and clinical disease activity. Cognitive impairment in particular tends to develop insidiously, irrespective of peripheral disease activity. Recent data from murine models and *in vitro* studies strongly support the role of specific autoantibodies directed against NMDAR, phospholipid, α tubulin, neuronal surface P antigen, and ribosomal P in NPSLE.[73] Anti-NMDAR and anti-P antibodies have been identified in the serum, CSF, and brain of SLE patients and have been associated with cognitive and depressive syndromes in some SLE patients. CSF anti-NMDAR antibodies have also been reported to be increased in patients with acute confusional state. The current challenge is to identify easily accessible, sensitive, and specific serological or imaging biomarkers for the diagnosis of CNS NPSLE syndromes that can also be used to monitor therapy.

PNS NPSLE events are recognized on the basis of clinical presentation with diagnostic studies such as electromyography and peripheral nerve biopsy.

Antiphospholipid antibody syndrome is described in detail in Chapter 61.

Drug-Induced Lupus

Until recently, drug-induced lupus referred to a clinical syndrome characterized by constitutional, musculoskeletal symptoms and serositis that resembles mild lupus and occurs after exposure to a number of drugs (most notably procainamide, hydralazine, chlorpromazine, and methyldopa). Drug-induced lupus has been associated with ANA and antihistone antibodies, whereas generation of more specific autoantibodies such as anti-DNA antibodies has been rare. Symptoms generally begin weeks to months after initiation of the inciting therapeutic agent and resolve within weeks after the drug is discontinued; autoantibodies can persist for up to 12 months. Host factors affecting drug metabolization (*e.g.*, slow acetylation of procainamide and hydralazine) contribute to the risk of developing drug-induced lupus. Multiple potential mechanisms resulting in the loss of self-tolerance have been suggested for this classic model. One of the most extensively explored is inhibition of DNA methylation with TLR activation, resulting in overexpression of costimulatory molecules such as leukocyte function–associated antigen-1 (LFA-1) on T cells and enhanced T-cell help.[74]

Since the introduction of anti-TNF agents, a different variant of drug-induced lupus has been recognized. Up to 30% of patients receiving TNF blockade develop autoantibodies, including a positive ANA and antibodies to dsDNA. A minority of patients develop anti-DNA antibodies, nephritis, and vasculitis. The pathogenesis of this immunological deregulation is not known.

Treatment

THERAPEUTIC PRINCIPLES

Goals of Therapy in SLE

I. Suppression of inflammation
  - Induction of remission
  - Maintenance of remission
  - Preservation of organ function

II. Suppression of immune activation
  - Modulation of the immune response

III. Treatment/prevention of drug-related toxicities

The goals of lupus treatment are to stop and reverse ongoing organ inflammation, to prevent or limit irreversible organ damage, and to suppress the immune response driving the inflammation and prevent flares. Therapeutic agents, and combinations thereof, can be used for induction of remission, maintenance of remission, or prevention of flare. The efficacy of therapeutic agents must be balanced against their potential toxicity. Thus treatment must be tailored to the individual patient based on disease manifestations. In general, milder disease requires treatment with less potent or lower doses of antiinflammatory and immunosuppressive medications than more active, severe disease affecting major organs such as the kidney or brain (Table 51.4). Individual patient responses to a given medication will vary, and patients must be monitored closely for response as well as toxicity.

"Treat-to-target" recommendations in SLE from an international SLE task force include the following more specific guidelines: the treatment target should be remission of organ manifestations; factors such as pain that negatively influences health-related quality of life should be addressed; maintenance treatment should aim for the lowest glucocorticoid dose needed to control disease; and relevant therapies adjuvant to any immunomodulation should be considered to control comorbidity in SLE.[75]

Some genetic factors predicting risk of toxicity or therapeutic benefit for individual agents have been identified. Polymorphisms of a key enzyme in the metabolism of azathioprine, thiopurine methyltransferase (TPMT), are common; 0.3% and 11% of Caucasians are homozygous and heterozygous, respectively, for mutations associated with altered expression of TPMT.[76] TPMT-deficient patients are especially susceptible to leukopenia and pancytopenia associated with azathioprine. Cyclophosphamide is metabolized to its active form by cytochrome P450. Individuals heterozygous or homozygous for a specific cytochrome P450 polymorphism (*CYP2C19*2*) have a lower probability of developing premature ovarian failure, but they also show a poorer response to therapy.[77]

Although corticosteroids are the foundation of treatment, exposure must be minimized to the greatest extent given their multiple and frequent side effects, including hypertension, diabetes mellitus, increased susceptibility to infection, bone loss, and weight gain (Chapter 86). Additional disease-modifying agents that are also steroid-sparing include antimalarials (hydroxychloroquine), antimetabolites such as azathioprine (1–2.5 mg/kg per day), methotrexate (7.5–25 mg/week), leflunomide (10–20 mg/day), and mycophenolate mofetil ([MMF], 2–3 g/day), and alkylating agents such as cyclophosphamide (monthly pulse 0.5–1.0 g/m^2) (Chapter 87). When more conventional therapies have failed, anecdotal reports, case series, and open-label studies suggest the use of intravenous immunoglobulin (2 g/kg over 2–5 days), thalidomide (50–100 mg/day), or cyclosporine (3–5 mg/kg/day). Medications such as dapsone, danazol, and chlorambucil may be efficacious in cutaneous disease, hematological disease, and in severe refractory disease, respectively, but in general these medications are not commonly used due to their toxicity and the introduction and availability of better-tolerated, efficacious agents. Belimumab, a monoclonal antibody directed against BAFF (Chapter 89), was approved by the FDA for treatment of SLE in 2011 and represents a therapeutic option for patients with nonrenal, non-CNS active disease.

A number of newer agents are on the horizon for treatment of SLE. Some are currently available but approved for other indications, whereas others are still in the developmental stages. These therapies, in general, have more specific immunological targets than standard treatments. Although multiple agents have been tested in animal models of disease, we will focus only on therapies that have been given to humans. Several of these agents have been recently evaluated in phase III clinical trials and have been unable to demonstrate superiority over treatment with placebo or standard of care. Although imperfect trial design may account for some of these failures, the possibility remains that these agents are not effective treatments for SLE and do not confer a substantial improvement over current standard-of-care therapies. Rituximab (anti-CD20 antibody), a B-cell–directed therapy approved for use in rheumatoid arthritis, targeting all B cells except plasma cells, failed to demonstrate improved performance over standard of care in trials of patients with active SLE, or in patients with active lupus nephritis added to a background therapy of MMF and corticosteroids. Elevated BAFF levels are present after B-cell depletion. These can exacerbate the impaired tolerance of SLE. Thus studies are ongoing to evaluate the efficacy of rituximab followed by belimumab. Abatacept (CTLA4-Ig), which is also approved for rheumatoid arthritis and blocks T-cell activation, was no better than placebo in trials of active lupus and of lupus nephritis, again added to background therapy of corticosteroids and MMF. A redesigned trial of abatacept for SLE is now being conducted. Epratuzumab (anti-CD22 antibody) targeting all B cells failed a phase III clinical trial. TACI-Ig, which blocks both BAFF and APRIL, is undergoing clinical study, although previous clinical trials were terminated prematurely because of infectious complications. Tocilizumab, an antibody to the IL-6 receptor, a cytokine involved in B-cell survival and activation as well as in differentiation of Th17 and Tfh cells, which is approved for RA, demonstrated unacceptable toxicity in SLE. Other agents in earlier clinical development are inhibitors of intracellular B-cell signaling molecules designed to block B-cell activation; R406, a SYK inhibitor; and Janus tyrosine kinase (JAK) inhibitors. The Jak inhibitors are being studied using topical administration for discoid lupus and oral administration for systemic disease.

Potential therapies aimed at DCs include vitamin D, which blocks DC maturation and T-cell activation, and inhibitory oligodeoxynucleotides, which block TLR9 signaling and DC maturation. However, a study of vitamin D supplementation designed to assess vitamin D inhibition of DC activation failed to demonstrate efficacy. Hydroxychloroquine, a standard agent for lupus, interferes with TLR7 and TLR9 signaling by preventing acidification of the endosomal compartment. A study of a novel RNase is under way.

TABLE 51.4 **Treatments for Systemic Lupus Erythematosus Disease Manifestations**

	NSAIDs	Antimalarials[†]	Low-Dose Corticosteroids (<0.5 mg/kg per day)	High-Dose Corticosteroids (>0.5 mg/kg per day)[‡]	Azathioprine	MMF	CTX
Constitutional	+	+	+		+		
Musculoskeletal	+	+	+		+	+	
Mucocutaneous		+	+				
Serositis	+	+	+		+		
Hematological			+	+	+		
Renal				+	+	+	+
Central nervous system				+			+
Vasculitis				+	+	+	+

CTX, cyclophosphamide; *MMF,* mycophenolate mofetil; *NSAIDs,* nonsteroidal antiinflammatory drugs.

[†] Antimalarials should be given to all patients to sustain remission and reduce damage.

[‡] High-dose corticosteroids are required for remission induction or an inadequate response to low-dose therapy.

Two studies of monoclonal antibodies against IFN-α failed to demonstrate efficacy; a trial of an antibody to the IFN receptor is under way.

Novel interventions directed at T cells include anti-CD40 antibodies, abatacept (CTLA4-Ig) in combination with cyclophosphamide for proliferative nephritis, and studies targeting ICOS, an inducible T-cell costimulator.

Therapies in development for other autoimmune diseases may also prove useful in SLE. Eculizumab, currently approved for paroxysmal nocturnal hemoglobinuria, is an antibody directed against C5 that blocks cleavage of C5 and the subsequent triggering of the complement cascade. Alicaforsen, an antisense oligodeoxynucleotide that inhibits ICAM-1 expression, decreases inflammation in both rheumatoid arthritis and Crohn disease. Efalizumab, a monoclonal antibody against CD11a (an LFA-1 subunit that interacts with ICAM-1), benefits patients with psoriasis. Although no chemokine-targeted therapies are in clinical trial in lupus, a CCR1 antagonist slowed disease progression in a mouse model of lupus and has been tested in patients with rheumatoid arthritis. FTY720, an agonist for the sphingosine 1 phosphate receptor that prevents egress of lymphocytes from secondary lymphoid organs and inflamed tissues, has beneficial effects in the MRL/*lpr* mouse model of lupus; it has been given to transplant recipients and to patients with multiple sclerosis. The use of anti-TNF-α agents for SLE is inhibited by its lupus-like effects in some patients. Paradoxically, TNF-α is involved in renal inflammation in SLE, and short-term treatment with monoclonal antibody to TNF-α appears to improve lupus nephritis, showing that agents can abort inflammation and yet exacerbate autoimmunity.

TRANSLATIONAL RESEARCH

ON THE HORIZON

- Increased understanding of the functional consequences of single nucleotide polymorphisms identified as susceptibility loci in systemic lupus erythematosus may provide insight into:
  - Dysregulation of tolerance mechanisms and pathogenesis of disease in different ethnic populations
  - Predictors of response to therapy
  - New therapeutic targets
- Development of organ-specific biomarkers will allow for improved use of immunomodulating and immunosuppressive therapies and possibly for use of preventive therapies.

Laboratory research continues to inform us about dysregulated immunological pathways in SLE. The current challenge of translational medicine is to shed light on the clinical relevance of these altered pathways. Increased understanding of the qualitative and quantitative differences of these molecular perturbations not only should result in improved diagnostic capabilities and biomarkers for disease, but also will lead to the ability to subset patients for prognosis and response to therapy. Improved organ-specific biomarkers and methods for subsetting patients on a molecular level are likely to result in improved use of immunological therapies. In particular the brain, which has been relatively inaccessible to mechanistic and diagnostic probing, is likely to be an organ to be more fully explored. Ultimately, advances in translational studies should result in more effective and less toxic therapeutic interventions.

CONCLUSIONS

In the past several years much has been learned about genetic susceptibility to SLE, and it is encouraging that many of the genes identified are associated with pathways that also have been implicated in disease pathogenesis. The role of B cells in disease pathogenesis has been confirmed, but recent studies have also highlighted the role of T cells, DCs, and neutrophils. Enhanced understanding of each of these contributing factors and the cross-talk between them has allowed identification of numerous potential therapeutic targets. The disappointing results from clinical trials of immunobiological agents for lupus have highlighted the critical importance of study design and the complexity of disease in humans. The overall goal in therapy must be to eliminate autoreactivity while maintaining immunocompetence. Among the challenges now faced are the careful phenotyping of patients to identify etiopathologically distinct subpopulations and new clinical trial designs to allow the use of combinations of agents, each of which alone may have a minor effect on disease course.

MULTIPLE-CHOICE QUESTIONS

1. Mortality in systemic lupus erythematosus (SLE)
   A. Has been stable for the past 4 decades
   B. Is greater in Caucasians than in other racial groups
   C. Is secondary to both the disease and the therapy

2. Autoantibodies in SLE
   A. Are an epiphenomenon
   B. Are generally tissue specific
   C. Form TLR-activating immune complexes

3. Treatment in SLE
   A. Relies on immunosuppression
   B. Is different for different races
   C. Has minimal toxicity

Rheumatoid Arthritis

Andrew P. Cope

Rheumatoid arthritis (RA) is one of the most common chronic inflammatory diseases and in modern times has become a prototype disease entity for defining the molecular and pathological basis of chronic inflammatory syndromes. The term *rheumatoid arthritis* was coined by Garrod in 1859. However, this was probably an inappropriate use of the term because it encompassed polyarticular osteoarthritis as well as inflammatory polyarthritis. In spite of references to inflammatory afflictions of joints by the likes of Galen, Sydenham, and Heberden, the first convincing case reports of the disease, described in terms that would be recognizable today, were published in 1800 by Landré-Beauvais, who labeled the disease "*la goutte asthénique primitive.*"[1] This description was distinct because all patients were female, an observation that was significant when the most important differential diagnosis at that time was polyarticular gout, a disease predominantly of males.

Today we recognize RA as a chronic inflammatory disorder of joints of unknown etiology in which the major target tissue is the synovial lining of joints, bursae, and tendon sheaths.[2] Although traditionally considered an autoimmune disease, RA differs from organ-specific autoimmune disease entities in several respects. From the outset of clinically apparent disease, the systemic immuno-inflammatory process, driven by cytokines and other inflammatory mediators, promotes the activation and proliferation of stromal joint tissues, in particular the fibroblastic synovial lining layer. This appears to contrast with organ-specific autoimmune diseases, such as type 1 diabetes or autoimmune thyroiditis, characterized by an antigen-driven immune-inflammatory response *in situ* leading to targeted cellular destruction of autoantigen-expressing pancreatic β-islet or thyroid tissue cells. In RA, once the inflammatory process is established, the inflammatory synovium, or pannus, may invade and erode underlying cartilage and bone. Unlike autoimmune diseases that target single organs or tissues, RA is a systemic inflammatory disease that likely encompasses a heterogeneous syndrome with marked variation in clinical expression that most clinicians today would acknowledge is more than one disease entity. Indeed, it is now apparent that the disease is heterogeneous not only clinically but also pathologically, serologically, and genetically.

EPIDEMIOLOGY

The incidence of RA (the rate of new cases arising in a given period) is 0.1–0.2 per 1000 of the population for males and 0.2–0.4 per 1000 for females.[3] Rates as high as 0.4 per 1000 have been reported when the 2010 American College of Rheumatology/European League Against Rheumatism (ACR/EULAR) classification criteria are applied. These rates plateau between the ages of 45 and 75 years in some series but can increase steadily with age until the seventh decade, declining thereafter. The largest difference in incidence between the sexes occurs in those under 50 years of age. Past evidence indicates that the incidence may be in decline, at least for seropositive disease. Large cross-sectional population samples indicate that disease prevalence, which ideally should include all past and inactive cases, ranges from 0.5–2% for Caucasian European and North American populations over the age of 15, with a female to male excess of 2–4 times.[3] Despite similar prevalence estimates for these geographically diverse populations, greater diversity has been documented for rural African populations, where the prevalence has been reported to be as low as 0.1%, and for Native Americans (including the Pima, Yakima, and Chippewa tribes), where the prevalence may be as high as 5%. Such variance across geographical borders likely reflects distinct environmental factors and sociodemographic determinants as well as a spectrum of genetic admixture. Lifetime risk has been estimated at 4% for women and 3% for men.

Complex polygenic autoimmune syndromes like RA are diseases of low penetrance, where thresholds of disease expression may be higher in males. This is based in part on the observation that the increased risk of disease in siblings of probands (denoted λs) is rather small; the λs for RA (risk to sibling divided by population risk) are estimated to be 3, whereas the λs for systemic lupus erythematosus (SLE) may be as high as 30; for celiac disease the λs are closer to 50. Recent insights into familial clustering indicate that family history remains a strong independent risk factor for RA but that this risk does not differ by gender.[4] This implies that nongenetic factors influence gender bias. Twin studies also provide compelling evidence for genetic effects, given the excess concordance rates for monozygotic (12–15%) compared with dizygotic twins (<5%, and probably nearer to 3.5%).[4] These concordance rates appear somewhat low, but compared with a background prevalence of 1% in outbred populations, genetic epidemiology studies report heritability estimates of 68% for those patients who carry antibodies to citrullinated protein antigens (ACPAs$^+$) and 66% for those who do not (ACPAs$^-$), indicating substantial genetic influence.[5] Human leukocyte antigen (HLA) is thought to contribute 35–40% of this value. This "missing heritability" leaves a substantial contribution to disease susceptibility from environmental factors, influenced by occupation, socioeconomic status, exposure to infectious pathogens, and lifestyle factors—a conglomeration of factors termed the "exposome."

KEY CONCEPTS

Important Risk Factors for Developing Rheumatoid Arthritis

- Female gender; impact of X chromosome, microchimerism, lifestyle
- Age; associated with accelerated immune aging
- Inheritance of genetic variants, *e.g., HLADRB1* and *PTPN22*
- Autoantibodies to citrullinated protein antigens (ACPAs), rheumatoid factor
- Family history; first-degree relatives have higher prevalence of genetic and serological risk factors
- Hormonal factors; nulliparity, the first 3 months postpartum, low androgen or high estrogen status (in males); longer-duration breastfeeding
- Smoking status; >25 cigarettes/day for >20 years confers a 15-fold risk in subjects who carry disease associated human leukocyte antigen (HLA)-DRB1 alleles
- Low alcohol intake
- Environmental antigens (the "exposome"); dietary factors; exposure to infectious (and noninfectious/microbiota) pathogens at mucosal surfaces such as the lung, periodontium, and gut; noninherited maternal antigens (NIMA)
- Urban dwelling

Two of the more intriguing factors contributing to disease occurrence are age and gender. Age-associated changes in susceptibility to infection, neoplastic disease, and autoimmunity suggest that a common mechanism could be responsible. Immune senescence is one possibility, where age-related decline in host immunity is characterized at the cellular and molecular level by dramatic expansions of lymphocyte clones, corresponding contractions of the naïve T- and B-cell repertoires, and telomere erosion of leukocytes, indicative of an extensive proliferative history.[6] When combined with oxidative stress and a range of biochemical derangements of pathways integral to antigen responsiveness and immune regulation, these factors may combine to (i) increase susceptibility to foreign pathogens, (ii) augment reactivity to self-tissue antigens (which may be modified post-translationally by the aging process), and (iii) generate a repertoire of lymphocytes defective in terms of tumor surveillance. Thus immune senescence could be considered a risk factor for RA.

The female sex preponderance implies that hormonal and reproductive factors strongly influence risk. On the one hand, nulliparity is a risk factor for RA. Women entering the first 3 months of the postpartum period are also at increased risk. By contrast, oral contraceptive use, pregnancy, and hormonal replacement therapy have all been associated with reduced risk or less severe disease,[7] whereas extended periods of breastfeeding appear to increase risk. Several possible immune mechanisms have been proposed. For example, maternofetal mismatch at the major histocompatibility complex (MHC) locus has been associated with higher disease remission rates during pregnancy. In contrast, noninherited HLA-DRB1 DERAA-positive (occupying the same amino acid positions as the QQRAA/QKRAA/KKRAA shared epitope motif) maternal antigens (NIMA) expressed on maternal cells constitute an environmental factor that is protective to a DERAA-negative child, perhaps through mechanisms relating to microchimerism. In mouse models pregnancy has been associated with quantitative changes in the numbers of regulatory T cells (Tregs). An influence of hormonal factors is further suggested in studies of men where disease is associated with lower androgenic testosterone and dehydroepiandrosterone (DHEA) levels, and increased estradiol, compared with healthy control male subjects.

ETIOLOGY AND PATHOGENESIS

Environmental and Nongenetic Factors

Most, but not all, studies have reported an association between RA and smoking. One of the largest studies comprising over 370 000 women from Women's Health Cohort Study reported a relative risk of 1.4 for women who smoked more than 25 cigarettes per day for more than 20 years, compared with nonsmokers.[8] The association appears to be more closely related to duration than to the amount of tobacco exposure, with smoking status being a risk factor for older age of RA onset;[9] smoking also may influence severity because smokers are more likely to have seropositive, erosive disease with extraarticular manifestations. The effect may be fully reversible in those individuals who stop smoking for 10 years or more. Further evidence of gene-environment interactions with respect to smoking have been documented in a population-based case–control study of Swedish RA patients.[10] In this study the relative risk of developing rheumatoid factor (RF) positive (RF^+) RA was calculated according to smoking status and HLA-DRB1 genotype. The relative risk of developing RA increased from 2.5 in nonsmokers with disease-associated HLA-DRB1 genes to 7.5 and 15.7 in smokers who carried one or two copies of the susceptibility alleles, respectively. Follow-up gene-environment interaction studies demonstrate robust associations between heavy smoking, HLA-DRB1 alleles encoding specific amino acids at positions 11 and 13, and the presence of ACPAs. Strongest associations were with antibodies to citrullinated α and β chains of fibrinogen (epitopes Fibα580–600 and Fibβ36–52) and α-enolase (CEP-1); IgA ACPAs were especially prevalent in smokers.

Being female, a smoker, and carrying specific disease-associated genetic variants may be necessary but not sufficient to initiate chronic inflammatory arthritis. Other environmental triggers may be involved. Not least among these is exposure to foreign pathogens. This association has gained credibility because of the presumed link between not only infection and autoimmunity but also immunodeficiency and autoimmune disease. Nonetheless, no single pathogen or group of pathogens has been defined. This could imply that aberrant host responses (either exaggerated innate inflammatory responses or failure to terminate such responses) may arise after a wide range of infectious insults. Indeed, bacterial products including superantigens, mycoplasma species, viruses (including herpes family, parvovirus, and retroviruses), and fungi have all been implicated, but data are insufficient to prove causation. Epstein-Barr virus (EBV) infection is common, antibodies to EBV nuclear antigens have been reported in patients with RA, EBV is a polyclonal activator of B lymphocytes, EBV-specific T cells reactive to EBV gp110 have been identified in RA synovial joints, and EBV RNA has been isolated from the synovium. There exists a tantalizing link between infection with *Porphyromonas gingivalis,* which expresses its own enzymatic machinery for generating bacterial or host-derived citrullinated proteins, severe periodontitis (which shares risk factors for RA), and RA.[11] According to this model, molecular mimicry is underpinned by autoimmune responses to bacterial-derived proteins such as enolase and cross-reactivity to the human orthologue α-enolase, expressed in abundance by myeloid cells in inflamed periodontal and synovial tissues.

A comparison of the microbial genomes from the small intestine and colon of mice housed in conventional versus germ-free facilities suggests that a single gut-residing species, in this case segmented filamentous bacteria, can profoundly influence the clinical expression of inflammatory arthritis in mouse models of autoimmune arthritis. In the K/B x N serum transfer model of arthritis, segmented filamentous bacteria enhanced generation of interleukin (IL)-17 expressing T cells in lamina propria.[12] Together with rapid advances in sequencing technologies, these data have prompted a systematic analysis of the symbiont microbial communities in patients with RA in comparison to those derived from healthy control populations. Microbiota are attractive environmental risk factors because they are acquired at around the time of birth and are modified by diet as well as the host genome. Studies from several groups have demonstrated irrefutable evidence of dysbiosis, with distinct patterns of microbiota depending on the stage of disease and the population studied. For example, the first US study reported enrichment of *Prevotella spp.* and *Bacteroides spp.*, gram-negative anaerobes in the gut of patients with early but not established RA. Metagenomic sequencing of oral and fecal microbiota from a cohort of Chinese RA patients revealed enrichment of *Lactobacillus*, particularly in severe disease, and depletion of *Haemophilus* species.[13] Interestingly, microbiota signatures were predictive of response to therapy, suggesting that their composition may be prognostic as well as indicative of the stage of disease. The prospect of fecal transplantation to prevent or treat established disease is an intriguing one.

Immunogenetics

RA is a clinically heterogeneous disease, and so comprehensive identification of disease susceptibility genes has been challenging, in spite of heritability estimates of at least 60%. With the exception of the MHC, where extensive gene polymorphism contributes about one-third of genetic susceptibility, and *PTPN22* (odds ratio 1.8), individual genetic variants confer low to moderate risk and have low penetrance (odds ratios in the range 1.1–1.5). Numerous genome-wide linkage scans of multiplex families with RA have established and confirmed an important contribution of the MHC (Chapter 5). This lends support to a wealth of epidemiological and genetic data describing associations between RA and specific HLA-DRB1 alleles, in particular HLA-DR4 subtypes. Although this association was first described by Stastny in the 1970s, it was shown more than a decade later that susceptibility to RA across different ethnic populations correlated closely with the expression of a specific consensus amino acid sequence (referred to as the "shared epitope," hereafter SE) within the HLA-DR β chain α-helix (Fig. 52.1).[14] This sequence was subsequently shown by several groups of investigators to be encoded by HLA-DRB1 alleles, including HLA-DR4 (*04:01, *04:04, *04:05, and *04:08), but also HLA-DR1 (*01:01), DR6 (*14:02), and DR10 (*10:01) alleles, among others. HLA-DR9

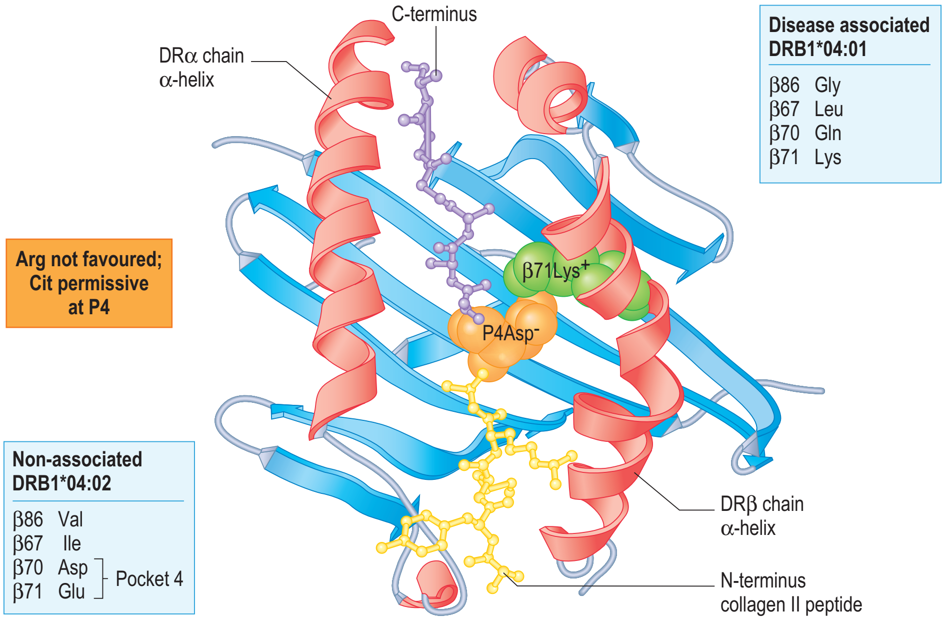

FIG 52.1 Crystal Structure of a Collagen II Peptide/Human Leukocyte Antigen (HLA)-DR4 Complex. Ribbon model of an immunodominant collagen II peptide (1168–1180) complexed to HLA-DR4 (DRA*01:01/DRB1*04:01); a view of the major histocompatibility complex/peptide complex as seen from the T-cell surface. DRα and DRβ chain helices are shown in red, whereas the β-pleated sheet comprising the floor of the peptide binding groove is shown in blue. Residues 67 to 74 of the DRβ chain, components of the third hypervariable region, derive the "shared epitope." The ball and stick model of the CII peptide is shown. Interacting residues of the peptide position 4 (Asp, orange) and DRβ chain residue (β71Lys, green), which make up part of pocket 4, are depicted as van der Waal's spheres. Differences in amino acid sequence between the closely related disease-associated DRB1*04:01 and nonassociated DRB1*04:02 gene products are illustrated. Note that although Arg would not be favored at position 4 in the peptide, modification of Arg → Cit by deimination would be permissive. Figure generated by R. Visse and A. Cope, based on crystal data derived by Wiley and colleagues (Courtesy Dessen et al, Immunity 1997;7:473.)

(*09) is also associated, but not in Caucasians. According to fine-mapping data, RA risk is linked not only to amino acids encoded by the RA SE sequence (71 and 74 positions of the alpha helix of the DRβ chain) but also to amino acid positions 11 and 13, located in the peptide binding groove of the HLA-DR heterodimer.[15] Single amino acid variants have also been defined in HLA-B (position 9) and HLA-DPβ (position 9). Differences in odds ratios associated with these five amino acid variants between ACPAs-positive and ACPAs-negative disease provide further evidence that seropositive and seronegative disease are genetically distinct. On the other hand, the finding of DERAA encoding HLA-DRB1 alleles (DRB1*01:03, *04:02, *11:02, *11:03, *13:01, *13:02, and *13:04), conferring lower disease risk, and more importantly the finding of reduced radiographic progression in RA even in the presence of one copy of the SE, raises the possibility that specific subsets of MHC class II genes may confer an independent protective role.

Specific genotypes cosegregate with distinct clinical features. For example, in population-based studies, different HLA-DRB1 alleles influence the severity of disease (including radiographic progression), with DRB1*04:01 being found in patients with severe, seropositive, erosive RA (often with extraarticular features such as vasculitis and Felty syndrome in *04:01 homozygous or *04:01/*04:04 compound homozygote individuals). Valine at position 11 of HLA-DRB1 confers the strongest association with radiological damage and highest all-cause mortality.[16] Statistical modeling points to HLA genetic polymorphism being associated with young-onset RA.[9] DRB1*01:01 and *10:01 are observed at a higher frequency in patients with less severe, seronegative, nonerosive disease. Inheriting two copies of alleles expressing the consensus sequence increases disease penetrance, time of onset, and severity. Thus these genetic associations manifest as clinically distinct disease entities.

On the basis of early observations, two principal models were proposed to account for the association between RA and the consensus DR β-chain sequence. Both were based on the assumption that the SE is the critical genetic element linked directly to disease. The first model proposed that the SE determines specific peptide binding and that "pathogenic" peptides bind only to disease-associated HLA class II molecules (Fig. 52.1). This model predicted that a gradient of affinities of disease inducing peptide for MHC class II molecules might account for the differences in susceptibility and/or severity conferred by different HLA-DR molecules. Along the same lines, disease-associated alleles may preclude the binding of peptides required for the generation of naturally occurring Tregs specific for self-peptide antigens. The second model proposed that the SE influences T-cell receptor (TCR) recognition by binding and selecting autoreactive T cells during thymic maturation and expanding these populations in the peripheral compartment; again perturbations of a repertoire of Tregs could arise through opposing influences of the SE sequence.

Two recent lines of experimental evidence provide further insights into HLA-disease associations. The first is the association between HLA-DR4 subtypes and telomere erosion in RA patients and healthy donors, detectable before the age of 20.[6] Telomere loss has been associated with aging and immune senescence. Whether this implies a direct contribution of HLA-DR4 expression to accelerated differentiation of hematopoietic cells in the context of a chronic inflammatory process is intriguing, but the relationship certainly warrants further investigation. The second line of evidence pointing to specific functions of SE^+ alleles has arisen through analysis of autoantibodies in RA patients typed at the HLA-DRB1 locus.[17] These studies, replicated in European and US RA cohorts, demonstrated associations between SE frequencies and antibodies to cyclic citrullinated peptides (anti-CCPs), as as opposed to rheumatoid factor (RF). Specifically, compared with healthy controls, the odds ratio for the association between one or two copies of the SE and anti-CCPs positivity was 4.4 and 11.8, respectively. These findings point to SE associating not with RA *per se,* but with a clinical phenotype, in this case autoantibodies to modified proteins.[17] An additional pathogenetic link between HLA and citrullination is supported by the observation that peptides carrying nonpolar residues such as citrulline (neutral), as opposed to arginine (positive charge), in pocket four of the HLA-DRαβ binding groove (see Fig. 52.1) convert a poorly binding peptide to a higher-affinity epitope that induces robust T- and B-cell responses *in vivo.* This notion is strongly supported by crystal structures of HLA-DRαβ (DRB1*04:01 and *04:04) complexed to peptide.[18] Here amino acids 11, 13, 71, and 74 form part of the fourth anchoring peptide binding pocket, the same positions that confer highest risk of disease, as noted above. Indeed, citrullinated human fibrinogen, but not the nonderivatized protein, induces chronic inflammatory arthritis in HLA-DR4 transgenic mice but not their nontransgenic C57BL/6 littermates. The importance of citrulline as a molecular feature of human T-cell–specific autoantigenic determinants is further suggested through identification of autoreactive $CD4^+$ T lymphocytes by flow cytometry using HLA-citrullinated-peptide tetramer complexes.[18] These tools also permit determination of the relative proportions of antigen-reactive effector and regulatory T-cell subsets.

Genome-wide association studies (GWASs) of large patient cohorts, stratified by autoantibody serology, have contributed significantly to our understanding of RA genetics. Meta-analyses and fine-mapping studies, including custom-designed SNP arrays covering nearly 130 000 genetic variants selected from 186 loci-poly defined in GWASs of autoimmune and immune-mediated inflammatory diseases (the Immunochip), have identified more than 100 susceptibility loci, many of which have been validated in RA populations of diverse ancestry.[19] Among the strongest associations outside HLA is *PTPN22,* initially identified in candidate gene association studies. The *PTPN22* gene variant confers risk with odds ratios ranging from 1.5 to 1.9 in Caucasian and European populations, and it is unusual among most genetic variants in that it is a coding frame mutation (R620W). *PTPN22* encodes a hematopoietic cytoplasmic protein tyrosine phosphatase whose substrates include Src and Syk family kinases, CD3ε, TCRζ, and signaling intermediates such as Vav.[20] It comes as no surprise that the *PTPN22* mutation, as a negative regulator of antigen receptor and integrin signaling, has also been described in type 1 diabetes, a subset of SLE patients, oligoarticular juvenile idiopathic arthritis, vitiligo, Addison disease, and autoimmune thyroid disease but not in multiple sclerosis or psoriasis. The link with autoimmune diseases associated with pathogenic autoantibodies is also intriguing. Whether the PTPN22-R620W variant is a loss- or gain-of-function mutant in man remains somewhat controversial. However, studies of Ptpn22-deficient mice, and mice expressing the R620W mouse orthologue Ptpn22-R19W, share features in T, B, and myeloid lineage indicative of loss of function for the R619W mutation, associated with increased antigen receptor signaling.[21] The relative contributions of the mutant to perturbationsin central and peripheral tolerance mechanisms remain to be determined.

Scrutiny of other, non-MHC susceptibility loci point to genes whose products are involved in proximal signaling pathways that regulate T-cell activation, differentiation, and persistence. Besides *HLA* and *PADI4*, which influence the molecular determinants of T-cell "input signals," these include *CD28*, *CTLA-4*, and *CD2-CD58* (regulation of T-cell costimulation); *CD247*, *PTPN22*, *PRKCQ*, *TAGAP*, and *REL* (transducer modules of TCR signaling); *STAT4* and *TNFRSF14* (inducers of lineage-specific cytokine gene expression and persistence of memory T cells); and *REL*, *IL2-IL-21*, *IL2RA*, and *IL2RB* (regulators of IL-2 gene expression and IL-2R signaling). Notable overlap with these and other allelic variants has been reported in other autoimmune diseases, indicating that susceptibility to RA is linked to fundamental perturbations of immune tolerance. Variants mapping to cell surface receptors (*IL6R*, *CCR6*, *CD40*, *CD5*, *FCGR2A*) and intracellular signaling intermediates (*TNFAIP3*, *TYK2*, *TRAF1*, *TRAF6*, *RASGRP1*, *BLK*) are well represented, as are transcription factors linked to cell differentiation and effector function (*GATA3*, *IRF5*, *IRF8*, *IKZF3*, *RBPJ*, *RUNX1*). Perturbations in expression or function of these genes will influence the function of a broad range of immune cell subsets.

Synovial Pathology

RA targets diarthrodial joints, structures characterized by hyaline cartilage lining opposing articulating surfaces and a cavity of viscous synovial fluid lined by synovial membrane lacking a basement membrane, but encased by a fibrous joint capsule. Normal synovial tissue comprises a lining layer, no more than a few cells in depth, of stromal fibroblast-like synoviocytes (FLSs—also known as type B synoviocytes) and sublining macrophages (type A synoviocytes). The synovium serves to line noncartilaginous surfaces, and although blood vessels are sparse, it functions to provide essential nutrients to avascular structures including cartilage, tendons, and bursae. Recent insights from synovial biopsies of "at-risk" subjects who have both joint pain (arthralgia) and serum RA-associated autoantibodies (*i.e.*, systemic autoimmunity) suggest that the transition from "normal" to inflamed synovium may occur over a period of only a few weeks or months.[22] Subtle T-cell infiltration was detected in those subjects who went on to develop clinically apparent synovitis.

Increased Vascularity and Cell Migration

The range of pathology observed in patients with RA perhaps most convincingly underscores the heterogeneity of the disease.[22] The earliest changes observed relate to increases in vascularity characterized by vascular congestion and thrombosis with obliteration of small vessels in association with perivascular inflammatory infiltrates. Hyperplasia of the synovial lining layer is another typical early finding. These changes are rather non-specific and certainly not diagnostic.

A key checkpoint defining the switch from acute to chronic persistent inflammation is the sustained activation of microvascular endothelium, phenotypic changes in the high endothelial venules (reminiscent of tissue injury), and the concomitant upregulation of adhesion molecules such as intercellular adhesion molecule (ICAM)-1 and vascular cell adhesion molecule (VCAM)-1 (Chapter 11). According to current thinking, the expression of chemoattractants derived from synovial stromal cells heralds the rolling, adhesion, and transmigration of mononuclear cells through endothelial barriers into the synovial membrane. It also contributes to the progressive synovial hypertrophy and hyperplasia, sometimes with villous-like projections more typical of chronic, established inflammation. Intravital imaging of synovial joints of mice injected with arthritogenic antibodies derived from the serum of *K/B* × *N* mice indicates that enhanced vasopermeability at sites destined to become arthritic is a crucial early event, at least in antibody-induced disease. This process is dependent on mast cells and neutrophils and on the release of the vasoactive amines histamine and serotonin, which contribute to heightened vascular permeability.

Neovascularization further promotes influx of inflammatory cells. To what extent this is driven by the hypoxic environment is not entirely clear, but angiogenic growth factors such as vascular endothelial growth factor (VEGF), angiopoietin, Tie-2, and hypoxia inducible factor (HIF), as well as lymphangiogenic factors VEGF-C and VEGF-R3, make important contributions. It has been proposed that influx of inflammatory lymphocytes and cells of monocytic lineage far outweighs the egress of cells from synovial tissue, likely due to chemokine gradients and engagement of sphingosine 1 phosphate receptor 1 (S1P1) by CD69 expressed on activated lymphocytes. This leads to downregulation of S1P1 and retention of cells in tissues. Once in the synovium, egress may be promoted by specific mediators such as sphingosine 1 phosphate, which actively regulates cellular egress, or blocked through integrin/adhesion molecule interactions, *e.g.*, between antigen-specific T cells and dendritic cells/APC, through TCR-dependent "stop" signals, or perhaps through highly selective and specific inactivation of chemokines by proteolysis, *e.g.*, stromal derived factor (SDF)-1 cleavage by cell surface dipeptidyl peptidase CD26. The abundance of lymphatic vessels in inflamed synovium, suggested by expression of podoplanin and CD31 *in situ*, suggests that active lymphangiogenesis exists that may promote efflux of cells and fluid from the synovium.[22] Interestingly, enhanced proliferation of lymphatic vessels and increased lymphatic drainage have been documented after tumor necrosis factor (TNF) blockade. Lymphatic growth factors such as VEGF-C (which signal through VEGFR-3/Flt-4) have been implicated in promoting this joint-protective effect.

Organization of Lymphoid Tertiary Microstructures

Tissue microstructure both dictates and facilitates immune responses in secondary lymphoid organs and mucosa-associated lymphoreticular tissues (MALTs). These structures have evolved to coordinate responses to pathogens and to direct lymphocyte recirculation, and although their role in immune homeostasis is established, quite how they contribute to pathological states is less well understood. Thus the inflamed synovium appears to be uniquely suited to supporting distinct patterns of cellular infiltrates—noncapsulated, as opposed to capsulated—inducible lymphoid structures, that could play a role in pathways of cell activation, differentiation, and survival.[22] These include diffuse, rather disorganized lymphocytic infiltrates which comprise the most common form of synovitis, occurring in ~30% in prospective cohort studies; up to 70% has been described in late-stage disease (at arthroscopy, joint replacement surgery). In 40–50% of patients more organized follicular structures may exist (Fig. 52.2). Based on immunohistochemical analysis, approximately 25% of these follicular structures include organized germinal centers in which there are zones of proliferating B cells with affinity maturation, in addition to a distinct T-cell zone. In aggregates lacking germinal centers, follicular dendritic cells (DCs) are absent.

A fourth histological pattern, characterized by granulomatous reactions, has been described in a much smaller subset of patients. The cellular and molecular determinants of these structures include the homeostatic lymphoid chemokines CXCL13 and the CCR7 ligands CCL21 and CCL19, VCAM-1$^+$ICAM-1$^+$LTβR$^+$ mesenchymal

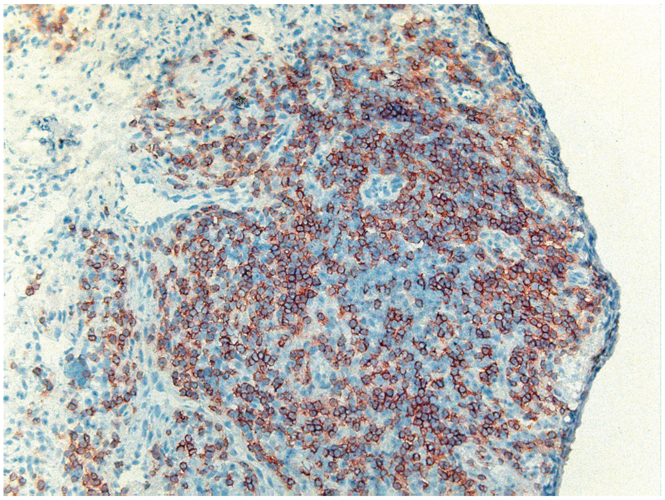

FIG 52.2 Lymphoid Follicular Structures in Inflamed Rheumatoid Arthritis Synovial Tissue. A characteristic hematoxylin and eosin–stained tissue section from a patient with active RA showing a large follicular-like structure (original magnification ×100). This section is also stained with monoclonal antibodies to CD3ε, followed by a three-step immunoperoxidase staining protocol ($CD3^+$ T cells stained dark red). (Courtesy Tak, et al. Arthritis Rheum 1996;39:1077, with permission from J. Wiley and Sons, Inc.)

organizer cells, and hematopoietic-derived $CD3^-CD4^+IL\text{-}7R^+RANK^+$ lymphoid inducer cells. Lymphoid tissue inducer cells produce LT-β, which is required for high endothelial venule differentiation, amplification of chemokine expression, and development of the stromal architecture. The mechanisms that sustain these lymphoid structures over time are not fully characterized but could involve persistence of antigen and augmented antigen-presenting function through the differentiation of follicular DCs, localized and autonomous expression of cytokines and growth factors, chemokine gradients favoring cellular interactions, and dysregulation of leukocyte homing and/or egress. Documentation of class-switch recombination and somatic mutation of immunoglobulin genes *in situ* is further evidence of active adaptive immunity within synovial lymphoid follicles, and suggests that supporting *in situ* production of pathogenic antibodies is of considerable pathobiological importance.

Cross-sectional studies have indicated that, from a clinical standpoint, these distinct patterns reflect not only the heterogeneity of the disease but also a spectrum of disease severity, with each pattern requiring a distinct targeted approach to therapy. More recent prospective studies, however, seem to indicate that the presence of lymphoid aggregates is one aspect of a rather dynamic process. Although the lymphoid aggregates are associated with the degree of synovial tissue cellularity and vascularity, they are neither diagnostic for RA nor predictive of radiographic outcome such as joint erosions. The dynamic nature of these lymphoid structures is supported by their dissolution after therapy with rituximab (anti-CD20) and TNF inhibitors, in the latter case enhancing lymphatic flow.

Gene Expression Signatures

Gene array technology has permitted unbiased and systematic analysis of synovial tissue at the whole-genome level and, as with genetic, serological, and histological analysis, has provided further evidence of disease heterogeneity. This strategy assumes that each disease phenotype should be represented in gene expression signatures of multiple genes. Remarkable variation in gene expression signatures has been observed, and initial reports seemed to suggest that these signatures could be divided broadly into two groups.[23] The first is characterized by upregulation of immune response and inflammatory genes; these tissues are enriched for MHC and immunoglobulin gene products. In some tissues this signature may resemble an antiviral response consistent with prior infectious insult and, more specifically, a signal transducer and activator of transcription 1 (STAT1)–dependent gene signature (promoting protective or proinflammatory effects).[23] This has also been observed in peripheral blood lymphocytes (PBL) from patients. The second group is more indicative of tissue remodeling, more reminiscent of that seen in osteoarthritis. Most interestingly, distinct fibroblast-like synoviocytes (FLSs), genotypes, and phenotypes match the type of RA tissue from which they derived. For example, FLS signatures from high-intensity inflammatory tissue resemble signatures of transforming growth factor (TGF)-β/activin-A–induced expression profiles in myofibroblasts, whereas growth factors such as insulin-like growth factor 2 and insulin-like growth factor binding protein 5 characterize FLSs from tissues with low-intensity inflammation. These data support the notion of RA heterogeneity being reflected in FLSs as a stable, if not transformed, trait. They would also be consistent with a model in which there is a transition from an antigen-driven phase of disease to a relatively antigen-independent process, characterized by autonomous, invasive, and aggressive FLSs and manifested as persistence of the inflammatory state. Subsequent disease flares might arise as a consequence of repeated exposure of lymphocytes to antigen after infectious or mechanical insult.

Gene expression signatures have clinical utility. For example, a type I IFN signature in peripheral blood cells negatively predicts the response to B-cell–depleting therapy rituximab, but its detection in neutrophils predicts a good response to anti-tumor necrosis factor (TNF) therapy. Enrichment of TNF-induced genes in early RA synovial biopsies is associated with higher disease activity and predicts poor response to first-line therapy, regardless of the drug therapy, while enrichment of synovial myeloid, but not lymphoid, gene expression signatures at baseline is associated with good clinical responses to TNF blockade at 16 weeks.

Aberrant expression of microRNA (miRNA) in cells or plasma of patients with RA has been widely reported,[24] with circulating miRNA, such as miR-223 and MiR-16, correlating with disease activity. This is of particular relevance because of the unique role for miRNA in regulating expression of multiple gene sets. A recent report indicates that baseline expression of miR-125b in peripheral blood mononuclear cells of drug-naïve early RA patients predicts response to therapy at 3 months.

Immunobiology of RA

Initiation of the Immune Response

Synovial fibroblasts are exquisitely sensitive to inflammatory cytokines such as IL-1, TNF-α, and IL-6. Accumulating evidence indicates that FLSs also express a range of toll-like receptors (TLRs) that can respond to exogenous, pathogen-associated molecular patterns (PAMPs) or indeed a growing range of self-tissue proteins, some of which could be considered damage associated molecular patterns (DAMPS). Endogenous ligands especially relevant to inflammatory arthritis include heat shock proteins, fibrinogen fragments, antibody-DNA complexes, high-mobility group box (HMGB)-1, and hyaluronan oligosaccharides. Recent data suggest that synovial FLSs, as well as synovial macrophages, express TLR2 *in situ.* Expression is upregulated after stimulation with IL-1 and the TLR2 ligand peptidoglycan. TLR2 engagement induces cytokines such as IL-6, matrix metalloproteinases, adhesion molecules, and an array of chemokines including granulocyte chemotactic protein (GCP)-2, RANTES, monocyte chemoattractant protein (MCP)-2, IL-8, growth-related oncogene-2 and, to a lesser extent, macrophage-inflammatory protein 1α, MCP-1, EXODUS, and CXCL-16. Data suggest that TLR3, TLR4, TLR7, and TLR9 are also expressed at messenger ribonucleic acid (mRNA) and possibly protein level[25] and may augment inflammatory cytokine expression by DCs from patients with RA.

DCs are thought to be the most important antigen-presenting cells in RA. Indeed, the proinflammatory environment favors DC maturation in regional lymph nodes as well as inflamed tissue.[26] Thus in peripheral blood, DC precursors express either an immature CD33$^{\text{dim}}$CD14$^{\text{dim}}$CD16^{-} phenotype or a more mature MHC class II$^{\text{bright}}$ CD11c^{+}CD33$^{\text{bright}}$CD14$^{\text{dim}}$ surface phenotype typical of conventional myeloid DC (mDC); neither population expresses costimulatory molecules. In contrast, synovial fluid and tissue DC subsets resemble mature peripheral blood cells; in addition, a subset expresses high levels of CD86 and can support allogeneic mixed leukocyte reactions. More recent data indicate that they may differentiate further *in situ* as suggested by nuclear translocation of RelB in DC localized within perivascular infiltrates, consistent with prior cytokine receptor or TLR engagement *in vivo.* Perivascular RA synovium also contains populations of MHC class II^{+}CD11c^{-}CD123^{+} plasmacytoid DC (pDC); in contrast to the conventional myeloid DC subset, these are RelB^{-} and comprise ~30% of all synovial DC. A subset of pDC express BDCA2, capable of producing IFN-α *in situ.* Unlike their peripheral blood counterparts, synovial pDC efficiently activate allogeneic T cells to proliferate as well as to produce IFN-γ, TNF-α, and IL-10.

Although the common myeloid precursor cell is the precursor for all myeloid cells, including DC and tissue macrophages, the precise role of monocytes—namely CD14^{+}CD16^{-}, CD14^{+}CD16^{+}, and the more recently described CD14$^{\text{dim}}$CD16^{+} subset—in synovial inflammation is uncertain. They are good candidates as persistence factors through their capacity to activate and polarize T-cell subsets, to respond to the environment through TLR expression, and to produce a wide range of inflammatory mediators, including IL-1, TNF, IL-6, IL-8, CCL2, NO, and type I IFN. In contrast a more recently described CD14$^{\text{dim}}$CD16^{+} subset may function to sense damage, to scavenge cell debris and higher-order molecular complexes, and to promote angiogenesis and tissue repair. More work is needed to establish the contribution of these distinct functional subsets to the chronic inflammatory process. Nonetheless, multiple cellular and molecular determinants exist in RA synovium that could serve both to initiate and perpetuate the immune inflammatory response.

This initial wave of inflammation has two major consequences. First, inflammatory cytokines will promote the activation of vascular endothelium, changes that occur very early in disease (see above and Fig. 52.3). Under the influence of locally generated cytokines and chemokines, synovial postcapillary venules undergo morphological changes to an extent that they resemble high endothelial venules similar to those observed in secondary lymphoid organs. The second major consequence is the migration of inflammatory leukocytes, including polymorphonuclear leukocytes and immature or undifferentiated monocytes, orchestrated by chemokines produced by resident stromal as well as infiltrating cells (Fig. 52.3). CXC, CC, C, and CX$_3$C chemokines all play a role, exerting chemotactic activity toward neutrophils, lymphocytes, and monocytes but also influencing the topology of inflammatory infiltrates. They are invariably early activation genes (*e.g.,* type I IFN response genes), in response to inflammatory stimuli. Besides the homeostatic chemokines described above, the key players include IL-8/CXCL8, RANTES/CCL5, MIP-1α/CCL3, SDF-1/CXCL12, IP-10/CXCL10, and MCP-1/CCL2.[27] Upregulation on endothelium of cell surface adhesion molecules, including ICAM-1, VCAM-1, and E-selectin, permits the rolling and adhesion of leukocytes as they migrate. In synovial joints, resident stromal cells and infiltrating macrophages are a dominant source of such factors. Crucially, the expression of cognate chemokine receptors such as CCR4, CCR5, CCR6, CXCR3, and CX3CR1 on inflammatory cell subsets contribute selectivity of cellular recruitment.[27] Within the T-cell compartment, there exist distinct profiles of chemokine receptor expression, patterns evolved perhaps to facilitate eradication of pathogens. For example, T-helper 1 cells preferentially express CXCR3 and CCR5; Th2 cells express CCR3; Th17 cells express CCR6 and CCR4; and Tfh cells express CXCR5. Data suggest that CCR5, CCR6, CCR7, CXCR3, CXCR4, and CXCR5 may all be important for B-cell migration into synovium. Together, these events characterize the acute phase of an innate immune response, a key checkpoint that precedes the progression to subsequent events that herald the onset of the chronic inflammatory phase.

Autoantigens in RA

Although current models of adaptive immune responses would suggest that DC carry antigens derived from damaged or dying synovial tissue, the molecular nature of disease-associated antigens has, until recently, remained an enigma. Many RA-associated autoantigens have been described (see Table 52.1 for examples), and for some there exist *in vivo* arthritis model correlates.[28] The best described are collagen II, proteoglycans, HCgp-39,

FIG 52.3 Cytokine Networks in Rheumatoid Arthritis. The pathogenesis of rheumatoid arthritis can be thought of as a series of complex and closely related pathways temporally and spatially regulated. These include (1) an acute insult that may trigger the disease, characterized by stimulation of FLSs by inflammatory stimuli and the generation of cytokines and chemokines that promotes the migration and infiltration by cells of the innate immune system; (2) repeated episodes of antigen-specific adaptive immune responses (in lymph node, bone marrow, and *in situ*). Failure to resolve adaptive immunity is a key checkpoint that may lead to (3) a cytokine-driven chronic inflammatory phase when multiple cellular and molecular components sustain the response. Through multiple pathways acting on many cell types, this process leads to tissue injury. Proinflammatory pathways are shown in blue (text) and red (arrows), whereas antiinflammatory, counter-regulatory pathways are shown in black (text and arrows). glucose-6-phosphate isomerase, α-enolase, vimentin, and citrullinated fibrinogen. However, when used as recombinant native antigen, few have been found to elicit reproducible and/or robust PB or SF T- or B-cell responses in a significant proportion of patients, as opposed to healthy donors. There are several plausible explanations for this. The most obvious is that antigens that drive autoimmune arthritis are not the same in mouse and man; another factor is that effector T-cell responses are more important very early but are blunted in established disease, or they may simply present at very low frequency. Another possibility is that the autoantigens used to test lymphocyte reactivity *in vitro* do not carry the posttranslational modifications (*i.e.*, the neoepitopes) recognized by autoantibody or antigen receptor. Good examples are the carbohydrate moieties of collagen II epitopes that serve as key TCR contacts in collagen II immunity, or the citrullination of key arginine residues in triple-helical CII or fibrinogen peptides that appear to be the immunodominant autoantibody epitopes. Utilizing MHC class II tetramers loaded with derivatized peptides, it has been possible to demonstrate in peripheral blood and synovial fluid from RA patients low frequencies of T cells (<1 per 10^6), recognizing citrullinated cognate peptides derived from aggrecan, vimentin, α-enolase, cartilage intermediate layer protein (CILP), and fibrinogen α and β.[29] The impact of posttranslational modifications on the cleavage of peptide epitopes is just beginning to be appreciated, but it is an attractive and highly plausible mechanism for the generation of self neoepitopes.

The Discovery of Citrulline as a Key Target for Autoimmunity in RA

In 1998, van Venrooij and colleagues first reported that patients with RA carried antibodies that recognized deiminated peptides of fillagrin,[30] the substrate that was found to be the antigen recognized in rat keratinized epithelium. This substrate formed

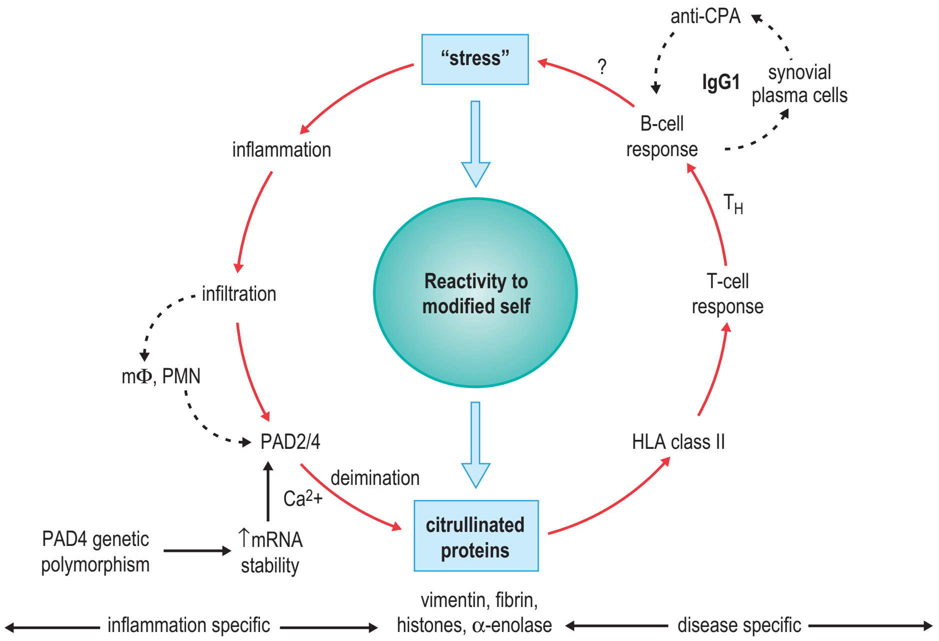

FIG 52.4 **The Generation of Autoantibodies to Citrullinated Protein Antigens.** The stressed and inflamed synovium is characterized by an influx of inflammatory cells, including macrophages and neutrophils that express peptidyl-arginine deiminases (PAD). In the presence of sufficient Ca^{2+}, PADs deiminate target proteins including, among others, vimentin, fibrinogen, aggrecan, type II collagen, histones, and α-enolase. This reaction is inflammation, but not disease-specific. The combination of environmental stimuli (including inflammation and exposure to tobacco smoke) and the inheritance of specific HLA-DRB1 alleles favor T- and B-cell immune responses to the host's derivatized neoepitope peptide antigens. Neoepitopes may also be generated by changes in peptide cleavage during antigen processing as a consequence of the Arg → Cit modification. Anti-CPA, autoantibodies to citrullinated protein antigens; T_H, T-helper effector cell.

the basis of the antiperinuclear factor (APF) assay, reported many years before. Using new-generation anti-cyclic citrullinated peptide (anti-CCP) based assays, the presence of these antibodies, now collectively termed ACPAs, is now confirmed to be both sensitive (up to 80%) and highly specific (>95%) for the diagnosis of RA.[30] Indeed, serum anti-CCPs levels are stable in established disease, they have been detected as early as 14 years before disease onset and have been shown to be predictors of radiographic progression. Changes in isotype usage and spreading of antigenic specificities suggest that the ACPAs response matures before disease onset. Citrullination is not specific for RA. Indeed, citrullination may be inflammation specific, because it has been documented in inflamed synovium derived from patients with reactive arthritis and psoriatic arthritis as well as RA, but not in those with OA. What appears specific for RA is the immune response to citrulline (Fig. 52.4). As outlined above, a link between ACPAs and HLA-DRB1 alleles, specifically SE$^+$ alleles, has now been established.[17] Linkage analysis across chromosome 6 has documented a peak with LOD scores in excess of 10 for ACPAs$^+$ patients but not for those that do not carry these antibodies. This relationship is independent of RF status, because the SE allele frequencies in ACPAs$^+$ patients are twice those of ACPAs$^-$ patients, even those patients who are RF$^+$. Indeed, the risk of carrying SE in RF$^+$ACPAs$^-$ patients is no different from that in the healthy control population. These data would be consistent with a model where T cells from patients with RA can recognize peptide autoantigens modified by citrullination if they carry SE$^+$ DRB1 alleles. Crystallographic studies suggest that the conversion of positively charged arginine at key residues in antigenic peptides from candidate autoantigens such as fibrinogen to neutral citrulline is permissive for peptide binding and recognition by autoreactive T cells *in vivo.*[18]

Finally, citrullination is widespread in multiple tissues in response to appropriate provocations. Although the molecular basis for these triggers is poorly understood, recent data point to a link between smoking—an environmental exposure known to be linked with RA—citrullination, and individuals carrying SE.[31] Thus cells derived from bronchoalveolar lavage from smokers, but not from nonsmokers, express citrulline. The association between the development of RA and smoking has now been linked to ACPAs$^+$ patients, whose relative risk increases 20-fold if they smoke and carry two copies of the SE$^+$ DRB1 alleles; in comparison, the relationship in ACPAs$^-$ patients appears to be much weaker or nonexistent. A second example relates to the fact that *Porphyromonas gingivalis,* a pathogen associated with severe periodontitis, expresses its own deiminating enzyme and has the capacity to modify host proteins such as fibrinogen and α-enolase in inflamed gingival tissue. Molecular mimicry is suggested by the finding that anti-α-enolase autoantibodies from patients with RA cross-react with *P. gingivalis*–derived α-enolase. The links between autoantibodies to the immunodominant α-enolase epitope CEP1, smoking, SE$^+$DRB1, and disease-associated *PTPN22* alleles are the strongest defined to date. These data are among the first to show a direct link between environmental exposure and disease-specific immune responses governed by immune response genes.

Lymphocyte Biology

Flow cytometric analysis of dissociated synovial mononuclear cell cultures indicates that infiltrating T lymphocytes make up approximately 10–35% of cells in inflamed tissue. The ratio of CD4 to CD8 T cells seen in peripheral blood is skewed in favor of the CD4 subset. Much of the information relating to phenotype and function is derived from detailed analyses of synovial fluid and, to a lesser extent, synovial tissue subsets. Similar enrichment of these subsets is commonly detected in PBL. Synovial T cells express phenotypic markers of antigen experienced, terminally differentiated T cells with enhanced migratory capacity. Thus synovial T cells typically carry cell surface markers such as HLA-DR$^+$, LFA-1$^+$, VLA-1$^+$, CXCR3, CD69$^+$, CD45RO$^+$, CD45RA$^-$, CD45RB^{dim}, CD29^{bright}, CD27$^-$, and CD25$^-$. Recent analysis of citrulline-reactive B cells from RA patients indicate that they display markers of class-switched memory B cells and plasmablasts (CD20$^+$CD27$^+$IgD$^-$). Analysis of the variable (V) regions of the immunoglobulin heavy and light chains confirm that antigen-specific activation and differentiation of B cells into plasma cells takes place in draining lymph nodes as well as in the chronically inflamed synovial tissue of patients with RA. Likewise, analysis of the T-cell repertoire indicates that the synovium provides a niche for supporting expansion of specific T cells, whose clonality is shared between different joints from the same patient, but not substantially with clones from paired blood samples.[32]

Analysis of synovial T cells reveals that expression of the TCR invariant chain subunits CD3ε and TCRζ is found at lower density than that found in corresponding peripheral blood T cells, evidence of prior antigen engagement. While synovial fluid T cells are also FasL$^+$, Bcl2$^-$, Bax^{bright}, favoring a proapoptotic state, it is thought that environmental cues transduced through common γ chain receptor signaling cytokines such as IL-2, IL-7, and IL-15, as well as type I interferons, prevent apoptosis of T cells *in situ.*[33] Synovial tissue–derived lymphocytes may be different. Consistent with their state of terminal differentiation, a subset of synovial T cells are CD28$^-$, while at the same time expressing a range of natural killer (NK) cell surface receptors that are thought to contribute to effector function independently of cognate antigen.

For over a decade it has been known that one of the dominant cytokines expressed in synovial T cells from patients with established disease is IFN-γ. Somewhat surprisingly, a significant proportion of IFN-γ$^+$ cells also express IL-10. Recent data support a model in which there exists, during differentiation, a transition from IFN-γ$^+$ Th1 T cells through an IFN-γ$^+$IL-10$^+$ double-positive stage to a single-positive IL-10$^+$ stage. This last phase could represent part of the normal lifecycle of an effector T cell, where IL-10 expression promotes the resolution of the adaptive immune response, attenuating the function of DCs. Interestingly data indicate that this Th1 lifecycle involving a switch from IFN-γ to IL-10 production may be defective in patients with active RA, providing an important mechanism for persistence of effector responses *in vivo.*[34] Treatment of RA patients with anti-TNF appears to restore IL-10 production through induction of specific transcription factors.[35]

Emerging evidence, supported by preclinical models, points to a role for IL-17 in the pathogenesis of inflammatory arthritis. Immunohistochemistry of RA synovium indicates that the dominant source is CD4 T cells, although γδ T cells, NK cells, and mast cells also contribute. Flow cytometric analysis reveals that the frequency of IL-17$^+$ T cells is less than that of IFN-γ$^+$ T cells and that a subset expresses both IL-17 and IFN-γ. The TNF$^+$IL-6$^+$IL-1$^+$–rich synovial environment is capable of supporting the differentiation of Th17 cells. Sustained IL-17 expression and stimulation of IL-17R–expressing stromal cells, macrophages, chondrocytes, and osteoclast precursors are implicated in promoting local tissue responses. These include induction of chemokines, matrix metalloproteinases, nitric oxide, and cyclooxygenase and promotion of osteoclastogenesis, which are key mechanisms underpinning pathways of cartilage destruction and bone erosion.

Molecular Basis of Persistence

Understanding the molecular basis of persistence is of major importance in diseases such as RA. It is now well established that enhanced expression of inflammatory cytokines is one of the hallmarks of chronic inflammatory diseases such as RA.[36] With few exceptions most cytokines are expressed in inflamed synovium at mRNA or protein levels. For example, unlike PBL from healthy donors, explants of synovial mononuclear cells constitutively express IL-1, IL-6, IL-8, granulocyte macrophage–colony-stimulating factor (GM-CSF), and a vast array of chemokines as well as growth factors including FGF, VEGF, and PDGF (Fig. 52.3). Although antiinflammatory or immunoregulatory cytokines, including IL-4, IL-10, IL-11, and TGF-β, as well as specific inhibitors of IL-1α/β (IL-1Ra) and TNF-α (soluble TNF-R) may also be detected, functional bioassays suggest that levels of these naturally occurring inhibitors may be deficient in relative terms. Indeed, levels of IL-1Ra and soluble TNF-R are significantly upregulated in synovial fluid compared with serum from patients with RA, and yet IL-1 and TNF bioactivity persists in spite of this, suggesting that attempts to suppress cytokine bioactivity are insufficient. The specific activity of cytokine subsets, their networks, and their contribution to RA are illustrated in Fig. 52.3. In many cases, the pathogenic roles of cytokines have been established in rodent models, either by selectively blocking their function (*e.g.,* with specific monoclonal antibodies or soluble receptor fusion proteins), by gene-targeting approaches, or by transgenesis.

Immune Regulation

Investigation of regulatory cell subsets and their antiinflammatory properties has perhaps more firmly established the concept that failure of the host's intrinsic mechanisms of immune regulation can underpin autoimmune diseases. Experiments in gene-deficient mice (*e.g.,* Foxp3, IL-2, IL-2R, IL-2R signaling, STAT5, IL-10, TGF-β) lend support to this concept. In RA the data remain less clear.[36] For example, there is *in vitro* evidence for a relative deficiency of constitutive IL-10 expression in synovial cell cultures, and yet clinical trials of IL-10 have been disappointing. These results may reflect the complex role of these cytokines in disease pathogenesis. The identification of defective numbers and/or function of CD4$^+$CD25^{bright} Tregs has been suggested by several investigators, but reports are conflicting.[37,38] Some studies have shown clear reductions in numbers of peripheral blood Tregs in patients with RA, whereas others have shown no difference; interestingly, Tregs appear deficient in cell number in subsets of children with juvenile idiopathic arthritis (JIA) whose disease tends to progress. In synovial joints, the data are more consistent, with many reports showing substantial increases in Treg numbers in synovial tissue and fluid compared with paired PB. However, some studies have reported normal function at a cellular level, whereas others have shown depressed regulatory function. An emerging concept, whose mechanism is yet to be proven, is that synovial effector T cells are refractory to regulatory pathways.

Impact of the Immune Response on Cartilage and Bone

For many years, it was considered that the terminal effector phase of chronic inflammation that led to cartilage destruction and bone resorption was driven almost exclusively by inflammatory cytokines and proteinases. IL-1, MMPs (MMP1, 3, 8, 13), and aggrecanases (ADAMTS 4 and 5) were, and remain, major culprits. Attempts to establish more directly a link between adaptive immunity and destruction of target tissue failed, not least because of the lack of a direct physical link between lymphocytes, chondrocytes, and bone. A breakthrough came in the late 1990s with the identification of the TNF/TNFR family member receptor for activation of nuclear factor (NF)-κB ligand (RANKL)/TRANCE/ODF and its counter-receptor RANK, and the dissection of the molecular and cellular components required for osteoclast differentiation from monocyte precursors.[39] According to contemporary paradigms, RANKL is necessary and sufficient for osteoclast differentiation. TNF, M-CSF, IL-1, and IL-17 contribute, and RANKL-independent pathways may also play a role. RANKL is expressed on synovial fibroblasts and osteoblasts but also on activated T cells, its counter-receptor being expressed on myeloid lineage cells including monocytes, osteoclast precursors, and DCs. Its expression is regulated by inflammatory mediators including TNF and PGE_2. RANKL is shed, probably through the action of several membrane-associated proteases including MT1-MMP (MMP14). Gene targeting of RANKL or RANK in mice leads to inhibition of osteoclastogenesis and a profound osteoporotic bone phenotype. Deletion of osteoprotegerin (OPG), the naturally occurring decoy soluble receptor for RANK, leads to unbridled osteoclast differentiation and bone resorption and substantially reduced bone mass. A good example of the link between adaptive immunity and bone resorption comes from cytotoxic T lymphocyte antigen-4 $(CTLA-4)^{-/-}$ mice, characterized by sustained chronic T-cell activation.[39] T cells from these mice overexpress RANKL. Importantly, the bone but not the inflammatory phenotype is rescued by inhibition of RANK/RANKL signaling. In RA, several studies have demonstrated perturbations of serum RANKL/OPG ratios, a parameter currently under investigation as a biomarker for bone homeostasis. Recent clinical experience with denosumab, a fully humanized monoclonal antibody that binds to RANKL, demonstrates increased bone mineral density and reduced bone turnover in patients with RA.

Distinct from enhanced bone resorption, bone formation is impaired in RA, although until recently the pathways involved were rather obscure. The inflammatory process itself, along with its effects on osteoblast maturation and function, has been directly implicated because bone formation at surfaces adjacent to bone marrow, as opposed to inflamed synovium, are relatively well preserved. Recent data also suggest that ACPAs can also directly promote osteoclastogenesis, providing a mechanistic link between autoantibodies and joint destruction that also depends on IgG glycosylation status.[40] Evidence now points to the canonical Wingless (Wnt) signaling pathway as being an essential control point in osteoblast function, based on the observation that in animal models of RA antibodies to dickkopf homologue 1 (DKK1), a secreted antagonist of Wnt blocking signals at the level of its cognate receptor Frizzled, promote bone formation and inhibit bone resorption indirectly by increasing production of OPG.[39] This indicates that Wnt signals negatively regulate osteoclastogenesis. Oxidative stress and hypoxia within the synovial compartment may contribute to attenuation of osteoblast-promoting *Wnt* signals.

The interplay between bone formation and resorption is fundamental to bone homeostasis, especially in the context of chronic inflammatory disease. Recent evidence suggests that the molecular basis for this so-called coupling lies with the osteoprotective factor semaphorin 3A. This factor regulates bone mass in both osteoblasts (through effects on the canonical Wnt/β-catenin signaling pathway) and osteoclasts (by inhibiting RANKL-dependent osteoclast differentiation).[41] Together these data support the view that bone and joint integrity are regulated by a delicate balance of catabolic and anabolic immune and inflammatory mediators influencing the maturation and function of osteoblasts (Wnt:DKK1) and osteoclasts (RANKL:OPG).

CLINICAL FEATURES

Disease Onset

RA is a heterogeneous disease that does not conform to a single clinical entity.[2] Whereas 10% of patients may have an acute severe onset and 20% a more subacute onset, the onset of signs and symptoms may be insidious in up to 70% of patients. A more episodic or palindromic onset has also been described. A common presentation, more likely during the winter months, will be that of a female in her fifth to sixth decade of life who complains of diffuse symmetrical joint pain, swelling, and stiffness of peripheral joints. Patients may complain that they can no longer make a fist, especially in the early morning. The targeting of afflicted synovial joints may be symmetrical in most but not all cases, typically affecting small joints of the hands and feet as well as wrists. Less frequent are those presenting with slow-onset monoarticular disease. Patients not fulfilling the diagnostic classification criteria for RA (see below) may, at this point, be ascribed the more appropriate diagnostic label of undifferentiated arthritis, because in a proportion of cases, signs and symptoms may resolve spontaneously. At 1 year, approximately 30% will progress to develop the syndrome recognized as RA. Systemic disease is much less common in current clinical practice, in part through application of earlier, more intensive treatment regimens (see below). Nonetheless, the systemic nature of the disease may be manifested through a wide array of systemic, extraarticular clinical features that may occur in patients with disease at the more severe end of the spectrum. A spectrum of disease severity may also be evident from hand radiographs; examples are shown in Fig. 52.5.

Diagnosis

Classification Criteria

The American College of Rheumatology criteria for the classification of RA are a set of clinical and laboratory parameters, established largely for epidemiological purposes, that serve as a guide for the diagnosis of RA. They are relatively straightforward and easy to apply, especially to patients with established disease. However, failure of a patient with early signs and symptoms of an inflammatory arthropathy to fulfill them does not mean that the individual does not have RA. The 1987 criteria were simplified further by removing the “probable,” “definite,” and “classic” subclassifications.[42] These criteria returned a sensitivity for RA of 91–94% and a specificity of 89% in the clinical setting. New criteria, established by a steering group comprising members of the ACR and EULAR and published in 2010,[43] are based on a

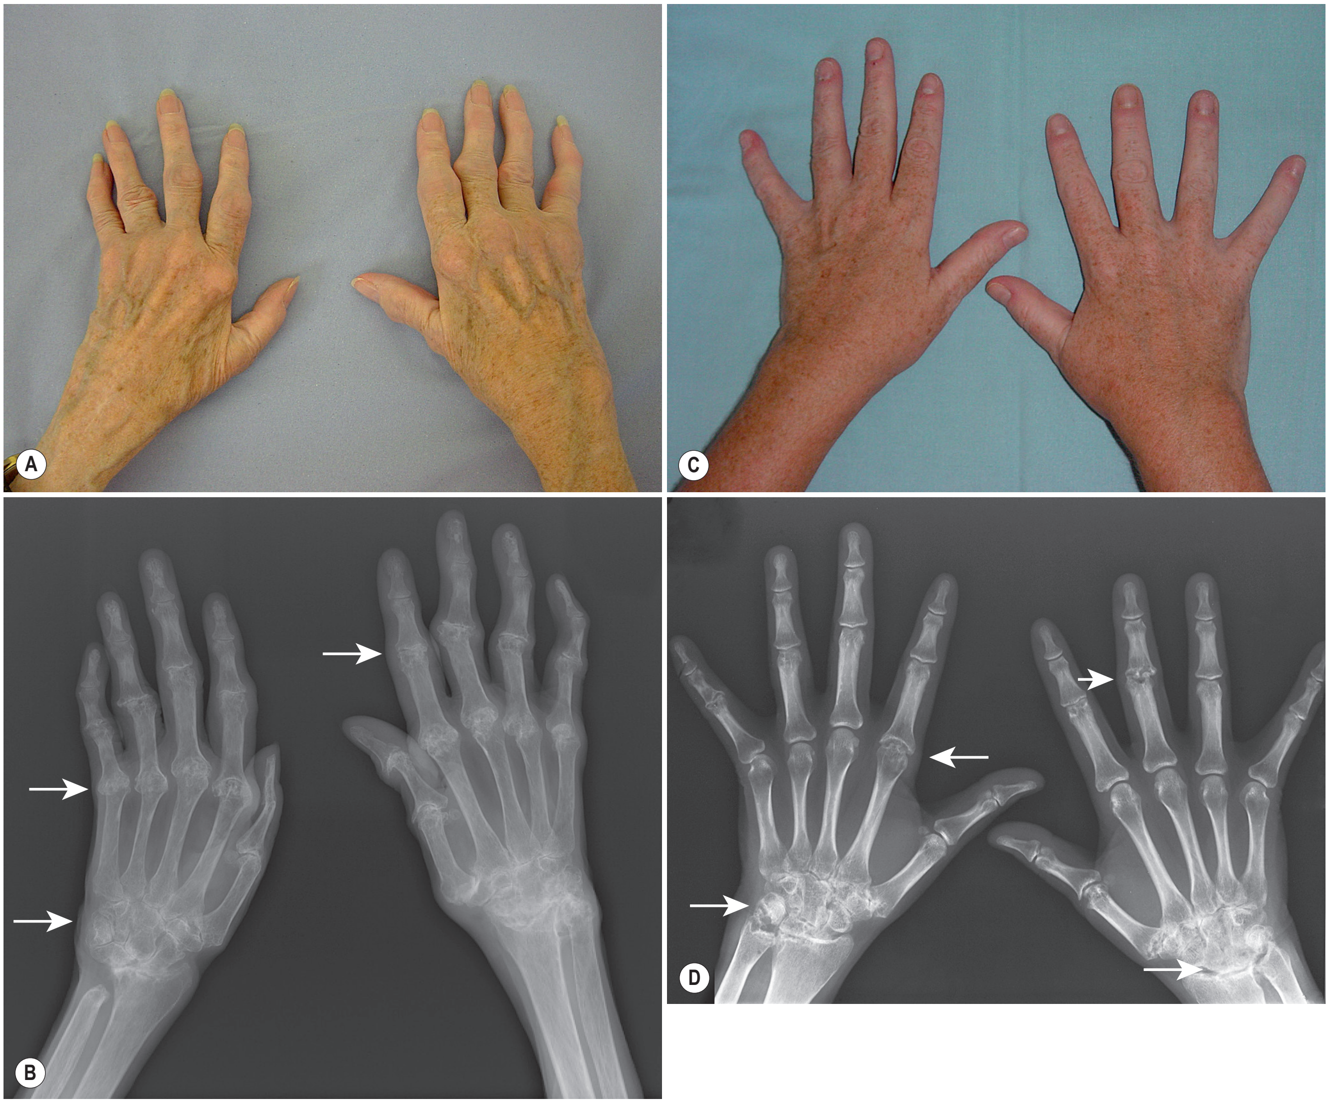

FIG 52.5 **Photomicrographs and Radiographs of the Rheumatoid Hand.** Chronic, severe, and erosive RA, refractory to treatment and showing joint swelling and classical deformities (A and B), is compared with erosive disease whose progression has been attenuated by combination and biological therapy (C and D). White arrows indicate major areas of bone and cartilage destruction. Reproduced with kind permission from the patients.

weighted score around four domains, including distribution and type of joint involvement (tender as well as swollen joints are included, scoring 0–5 points), serology (0–3) that includes RF or ACPAs and is weighted according to antibody levels, duration of synovitis (0–1), and acute-phase reactants erythrocyte sedimentation rate or C-reactive protein (0–1). A score of 6 or above is indicative of an early disease state requiring initiation of disease-modifying antirheumatic drugs (DMARDs) such as methotrexate (Table 52.2),[43] and so these criteria are thought to better reflect an intention to treat on the part of the supervising physician. Although the presence of synovitis in at least one joint is required (in the absence of an alternative diagnosis that better explains the synovitis), there remains debate as to whether subclinical synovitis of specific joints, defined by magnetic resonance imaging (MRI) or high-resolution ultrasonography (HRUS), should be included in the joint score.

Laboratory Findings

Until the late 1990s, IgM RFs, autoantibodies that recognize the Fc subunit of IgG, remained one of the few parameters of value in the clinical setting, forming the basis of the seropositive versus seronegative RA stratification and identifying those patients more likely to progress to erosive disease with or without extraarticular features. Nevertheless, RF can be detected in up to 5% of the healthy population and in 10–20% of the elderly population (>65 years of age); RF is found in a range of rheumatic conditions including Sjögren syndrome, SLE, and cryoglobulinemia as well as in acute infectious and neoplastic disease entities, influencing its diagnostic utility. In general RF is not of value for monitoring responses to therapy.

The discovery of ACPAs, which can be detected very early in the disease process, has had a major impact on diagnostic practice as the assays have become more widely available.[30] They also

have prognostic value in terms of radiographic progression, and titers may alter with therapy. The new-generation anti-CCPs kits have demonstrated diagnostic sensitivity of 80% and specificity of 98%. As the range of RA-associated autoantigens has expanded and the repertoire of citrullinated target autoantigens has become better defined, multiplex assays of serum autoantibodies are likely to play an increasingly important role in the diagnosis and prognosis of subsets of autoantibody-positive inflammatory arthritides.

CLINICAL PEARLS

Predictors of Poor Outcome in Rheumatoid Arthritis

- Chronic, unremitting disease onset, especially at advanced age
- High disease activity scores at baseline
- Female gender
- Poor functional status as determined by validated functional disability indices such as the Stanford Health Assessment Questionnaire (HAQ) and the Arthritis Impact Measurement Scale (AIMS)
- Low socioeconomic status
- Systemic and extraarticular features
- Depression and anxiety
- Comorbidity, *e.g.,* infection, cardiovascular disease, renal impairment
- Early erosive disease (in first 6–12 months; may be associated with ACPAs autoantibodies)
- Persistent acute-phase response (*e.g.,* time-integrated CRP levels)
- Autoantibodies (RF and ACPAs) and HLA-DRB1 status (SE$^+$)
- Significant delay in early use of DMARDs and corticosteroids

ACPAs, antibodies to citrullinated protein antigens; *CRP,* C-reactive protein; *DMARDs,* disease-modifying antirheumatic drugs; *RF,* rheumatoid factor; SE, shared epitope.

Insights Into the Preclinical Phase of Disease

ON THE HORIZON

The Preclinical Phase of Rheumatoid Arthritis

- High-risk individuals include those with inflammatory joint pain (arthralgia) and serum RA–associated autoantibodies. From 40–50% of those with high-titer ACPAs (with or without rheumatoid factor) may develop clinical synovitis within 24 months.
- Targeting these high-risk individuals with preventative strategies provides the best chance of achieving cure. Trials of rituximab, abatacept, or hydroxychloroquine are ongoing.
- In-depth molecular and cellular studies for characterizing the preclinical phase of disease will be critical to the success of this endeavor.
- Models for progression to RA have identified the following phases:
  - (I) Genetic risk
  - (II) Genetic risk with autoimmunity (*e.g.,* ACPAs, rheumatoid factor)
  - (III) Genetic risk with autoimmunity and arthralgia (but absence of clinically apparent synovitis)
  - (IV) Undifferentiated arthritis (clinically apparent synovitis, not fulfilling RA classification criteria)
  - (V) Early RA (fulfilling disease criteria; need for DMARDs)
- Stratification of risk, including genetic, serological, and demographic factors, will permit the identification of subjects most suitable for intervention studies.
- Studying the impact of lifestyle modifications, *e.g.,* diet, stopping smoking, would be of great interest.
- Reestablishing immune homeostasis and/or induction of immune tolerance may provide the best chance of achieving cure in subjects during the preclinical phase of disease. Early-phase studies of peptide immunotherapy indicate that this approach is well tolerated.
- Establishing robust assays for signatures of immune tolerance (*e.g.,* immune phenotyping by flow cytometry, extended autoantibody serotyping, multiplex assays for detection of inflammatory mediators in serum, whole-blood transcriptomic profiles) that reflect a healthy immune system will greatly facilitate these endeavors.

ACPAs, antibodies to citrullinated protein antigens; *DMARDs,* disease-modifying antirheumatic drugs; *RA,* rheumatoid arthritis.

The identification of a preclinical phase of RA, through the detection in serum of autoantibodies up to 14 years before disease onset, has sparked considerable interest in characterizing the RA prodrome in more detail. Work has centered around evaluation of acute-phase proteins and serum cytokines and chemokines, which appear to rise 1–2 years before onset of clinical disease; ACPAs isotype usage and epitope spreading; whole-blood gene expression analysis, which shows similarities to patients with established disease (including type I interferon-inducible gene signatures in a subset); imaging by MRI and ultrasonographic modalities; and, most recently, analysis of lymph node immune phenotypes, showing evidence of lymphocyte activation. The strongest predictors of progression in those at-risk subjects are joint pains without clinically detectable synovitis (arthralgia) combined with the presence of high-titer ACPAs and RF autoantibodies. Risk scores, which take into account other demographic factors, have been developed and are currently being evaluated. Progression rates for ACPAs$^+$ arthralgia patients with subclinical synovitis detected by ultrasound examination are of the order of 20% over a median of 28 months,[44] while arthritis-free survival curves suggest that 40–50% of those at highest risk will develop clinically apparent synovitis in 2–3 joints within 24 months. This rate of progression is considered to be sufficient to justify secondary prevention intervention studies. Somewhat surprisingly, genetic markers, such as HLA-DRB1 SE, have not contributed dramatically to risk estimates.

TREATMENT

Disease-Modifying Antirheumatic Drugs

THERAPEUTIC PRINCIPLES

Treatment Paradigms in RA

- Education and counseling through early involvement of a multidisciplinary team, including specialist nurse and other health care professionals; appropriate balance of rest and exercise during disease flares
- Adequate nutrition (especially important with severe, active disease)
- Comprehensive assessment of disease activity, especially during early phase of disease to achieve rapid disease control
- Complete suppression of inflammation early in the disease, with tight control through regular and frequent reassessments focused around disease activity scores
- Yearly imaging assessments, *e.g.,* X-rays or high-resolution ultrasonography of hands and feet to monitor radiographic progression
- Early use of DMARD/SAARDs
- Early use of corticosteroids, including use of intraarticular joint injections to suppress inflammation, and use of step-up combination therapy in severe disease
- Appropriate use of biologicals, *e.g.,* early use of anticytokine, T- or B-cell–targeted therapies in severe disease
- Early relief of pain with judicious use of NSAID or COX2 inhibitors according to safety/risk profile
- Monitoring for drug toxicity
- Effective contraception, where appropriate
- Bone protection
- Monitoring for risk factors of key comorbidities, including cardiovascular disease
- Prevention of infection through vaccination (preferably before instituting immunosuppressive agents), *e.g.,* against influenza, pneumococcus, and herpes zoster

COX, cyclooxygenase; *DMARD,* disease-modifying antirheumatic drugs; *NSAID,* nonsteroidal antiinflammatory drugs; *SAARD,* slow-acting antirheumatic drugs.

Over the past two decades there has been a dramatic paradigm shift in the therapy of RA from control of symptoms to the control of the disease process and aggressive suppression of inflammation. This shift has come about through a growing appreciation of the relationship between joint inflammation and joint destruction and also through the development of imaging technology that has documented evidence of erosive changes within the first 6–12 months of disease. The impact of this paradigm shift in therapeutic terms is striking. Traditional "go-low, go-slow" regimens of the 1970s and 1980s included the initiation of nonsteroidal antiinflammatory drugs (NSAIDs), followed by implementation of DMARDs only after destructive disease became evident. Depending on the clinical response, sequential monotherapy was the norm. Although this strategy may still be appropriate for patients with mild disease, current practice now dictates aggressive combination therapy (two or more conventional DMARDs) from the outset for patients with poor prognostic factors, with preference for the faster-acting DMARDs such as methotrexate, leflunomide, and sulfasalazine (onset 3–6 weeks) over slower-acting agents such as hydroxychloroquine, gold, and D-penicillamine (onset 3–6 months), but with the addition of oral or parenteral prednisolone. More recent data suggest that the specific choice of therapy may be less important than the strategy. For example, the TICORA and BeST studies both indicate that intensive treatment when combined with intensive control most convincingly influences outcome measures, including clinical response, retention, functional status, and radiographic progression. The benefits of tight control have been substantiated in many subsequent clinical trials as well as in "real life" clinical practice.[45,46]

Anticytokine Therapy

The introduction of targeted therapy to the clinic using biological agents (*e.g.,* chimeric or fully humanized antibodies to ligands or receptors, soluble receptor fusion proteins, or recombinant receptor antagonists) has transformed the treatment of RA. The prototype biological is TNF-α blockade.[47] The rationale for inhibiting TNF-α bioactivity is based upon its pleiotropic effects on cell activation, cellular adhesion and migration, induction of cytokine and inflammatory gene mRNA and protein, neoangiogenesis, and the regulation of cartilage catabolic factors such as IL-1 and matrix metalloproteinases (Fig. 52.3). TNF-α and other inflammatory cytokines such as IL-1, IL-6, IL-15, IL-17, and GM-CSF are expressed constitutively in inflamed synovial tissue at mRNA and protein level. In many cases the expression of their high-affinity cognate receptors is upregulated and the functional activity of the corresponding naturally occurring inhibitors (*e.g.,* soluble TNF-R or IL-1Ra) is reduced (although levels of protein may be increased, reflecting an attempt at restoring homeostasis). As proof of principle, inhibition of cytokine activity, including TNF-α, IL-1, IL-6, IL-15, and IL-17, have all been shown to have benefit in animal models of arthritis.

Chimeric anti-TNF monoclonal antibodies (infliximab) were first used to treat RA in open-label clinical trials in 1992.[47] Humanized antibodies (adalimumab) and the soluble p75 TNF-R IgG fusion protein (etanercept) were tested subsequently with comparable therapeutic effects; golimumab and a construct comprising a PEGylated anti-TNF antibody Fab fragment (certolizumab) are also licensed for use in patients with RA, as are a growing number of "biosimilar" TNF inhibitors. TNF-α blockade leads to dramatic and rapid reductions in symptoms (pain, stiffness, and fatigue) and signs (joint pain and swelling) of arthritis in a dose-dependent fashion, and in a significant proportion of patients (~60–70%) who have failed conventional DMARDs.[47] As a class, these biological agents can be used repeatedly, and when used in combination with methotrexate, they are superior to either drug alone. The mechanism is not clear but may be related to reductions in immunogenicity of the therapeutic antibody (the antidrug antibody [ADA] response), effects on the half-life of the biological, or perhaps the combined immunological effects of anticytokine and anti-T-cell agents. Radiographic progression may be attenuated, even in subsets of patients with poor clinical responses; in some patients radiographic scores improve, suggesting that healing of joint tissues may take place. TNF-α blockers when used early demonstrate superior remission rates. Some studies have shown that a significant proportion of patients remain in remission even after withdrawal of anti-TNF, providing evidence suggestive of immune modulation. Regardless of the TNF inhibitor used, the contribution of TNF to host defense is further suggested by an approximately twofold increased risk, especially during the first 6 months, of serious infections of the upper respiratory tract, skin, and joint as well as by a significantly increased risk of reactivation of latent tuberculosis. The global risk of malignancy, particularly lymphoma, which already is increased in the RA population as a whole, does not appear to be increased with anti-TNF therapy, although an increased risk of melanoma has been reported through biologicals registries. The development of antinuclear antibodies in 8–15% of patients, as well as rare cases of demyelination, points to effects that may be related to restoration of autoimmune responses in predisposed subjects after TNF-α inhibition.

The clinical benefit of TNF-α blockade has prompted extensive mechanism of action studies.[47] Anti-TNF reduces the acute-phase response, including IL-6 serum levels. Leukocyte trafficking is inhibited, as demonstrated through an early (within hours) and dramatic rise in lymphocyte counts through demargination, a more prolonged and sustained exclusion of leukocytes based on reductions in cellularity of synovial tissue biopsies after treatment and suppression of markers of angiogenesis, including VEGF; TNF blockade promotes lymphangiogenesis and may facilitate cell egress from inflamed synovium. TNF-α blockade has also been shown to downregulate markers of cartilage and bone destruction, including the collagenases MMP1 and 3, and to reduce the ratio of RANKL and OPG in serum, effects that might explain in part the joint-preserving effects of anti-TNF *in vivo.* Finally, there is additional evidence of anti-TNF-induced immune homeostasis, based on restoration of cell-mediated immune responses to recall antigens as well as mitogens, but also on an increase in both the numbers and function of $CD4^{+}CD25^{high}$ Tregs and on increases in expression of the immunoregulatory cytokine IL-10.[35,37] This effect could be explained in part by the effect of TNF blockade on restoring the expression of the Treg-associated transcription factor FOXP3.

The IL-1 receptor antagonist (IL-1Ra) is the only IL-1 inhibitor currently licensed for use in RA. It has disease-suppressing effects in animal models of arthritis, with potent joint protection, but has proven less effective than anti-TNF in patients with RA. Nevertheless, it has been used effectively to treat patients who have failed TNF-α blockade, slowing radiographic progression, and may be efficacious in a subset of individuals with systemic autoinflammatory syndrome–like features. Anti-IL-6R blockade (tocilizumab) is licensed for use in patients with established RA. Evidence suggests that in early disease, tocilizumab as monotherapy is as effective in suppressing signs and symptoms of RA as when it is combined with methotrexate. These effects are mediated through blocking IL-6 actions on the immune response, the acute-phase response, osteoclastogenesis, B-cell activation and immunoglobulin production, angiogenesis, and cell adhesion (reviewed in Kishimoto).[48] Clinical responses are comparable to those observed with TNF blockade. Unlike in psoriasis, the effect of inhibiting IL-17 in RA (with humanized monoclonal antibodies ixekizumab or secukinumab that block IL-17A) has been more modest, although there may exist a subset of RA patients in whom IL-17-driven inflammatory responses dominate. A role for blocking GM-CSF is awaited. Blockade of cell adhesion or chemokine function has proved disappointing in RA for reasons that may lie in the redundancy of these complex systems.

Finally, the impact of using small molecule inhibitors of cytokine signals, transduced through receptors that utilize members of the Janus kinase (JAK) family of tyrosine kinases,[49] has been evaluated in some detail. These are interesting, immunologically important kinases, because gain-of-function mutants are associated with leukemia and lymphoma, whereas loss-of-function is associated with primary immunodeficiency. Jakinibs, including tofacitinib and baricitinib, have been studied in phase III clinical trials of RA patients. Tofacitinib has high affinity for JAK3 but is also able to partially inhibit JAK1 and, to a lesser extent, JAK2; baricitinib blocks JAK1 and JAK2 to a similar extent. Tofacitinib has been studied in head-to-head studies with methotrexate and with TNF inhibitors. In methotrexate-naïve patients, tofacitinib was superior to methotrexate in reducing signs and symptoms of RA and in inhibiting the progression of structural joint damage. In patients taking background methotrexate therapy, tofacitinib was similar in efficacy to adalimumab. JAK1- and JAK3-selective jakinibs are under evaluation. Inhibition of another kinase, spleen tyrosine kinase (Syk) with R788 (fostamatinib), has also shown clinical efficacy in RA.

Anti-T-Cell Therapy

The contribution of costimulatory signals (“signal 2”) transduced through CD28 to priming and activation of naïve T cells and amplification of cytokine gene expression and proliferative responses has provided a rationale for testing costimulatory blockade in patients. This has been achieved using a nondepleting humanized IgG1-CTLA-4 fusion protein that prevents CD80 and CD86 (expressed on antigen-presenting cells) from engaging CD28 (but also CTLA-4) expressed on T cells. Initial studies confirmed that the agent was safe and well tolerated.[50] When administered as an intravenous infusion on days 1, 14, and 28, and then monthly thereafter at a 10-mg/kg dose in combination with methotrexate, 60% of patients achieved a 20% improvement in tender or swollen joint counts as well as 20% improvement in three of the other five ACR criteria (ACR20) compared with 35.3% of controls; ACR50 responses were 36.5% versus 11.8%, respectively. CTLA-4-Ig (licensed as abatacept) has since been shown to inhibit radiographic progression and structural damage by ~50%, and it is also effective in treating those patients who have had inadequate responses to TNF blockade as well as to methotrexate. Abatacept can also be administered subcutaneously on a weekly basis with efficacy comparable to that of the intravenous preparation. From an immunological standpoint the data are interesting in several respects. First, head-to-head studies indicate that the kinetics of response are remarkably similar to those of anti-TNF. This likely reflects the significant number of costimulation-dependent T cells actively participating in the ongoing inflammatory response. Clinical improvement may continue beyond 12 months. Second, recent data suggest that inhibition of CD28 signals does reduce the number of Tregs, as might have been predicted from mouse studies.

Anti-B-Cell Therapy

Rituximab is a humanized monoclonal antibody that recognizes human CD20, a 33- to 37-kDa membrane-associated phosphoprotein expressed on pre-B, immature, and mature B cells but not on plasma cells. It was initially developed, and then licensed, for the treatment of non-Hodgkin lymphoma. While CD20 ligation promotes B-cell activation, differentiation, and cell cycle progression, the function of CD20 is still poorly understood. The therapeutic effects of anti-CD20 are related to B-cell depletion, which can vary between patients due to antibody-dependent cell cytotoxicity, complement-mediated cell lysis, and/or triggering of intracellular pathways for apoptotic cell death.[51]

The initial open-label studies in RA patients combined rituximab with cyclophosphamide and steroids, and so the precise contribution of rituximab to the clinical response was unclear. A pivotal placebo-controlled trial of rituximab therapy randomized 161 patients with RF-positive RA to compare the efficacy and safety of methotrexate alone (standard therapy) versus methotrexate plus rituximab (1000 mg on days 1 and 15), rituximab alone, or rituximab plus cyclophosphamide.[51] All groups received a 17-day course of steroids, which may facilitate B-cell depletion. Up to 43% of patients receiving the combination of rituximab and methotrexate achieved 50% improvement in clinical and laboratory parameters after 24 weeks (ACR50), and this was at least as good as the rituximab/cyclophosphamide combination (41% achieving ACR50) and superior to methotrexate (13%) or rituximab alone (33%). The overall incidence of infection was similar across treatment groups, but serious infections were reported in rituximab-treated patients. Postmarketing surveillance has documented progressive multifocal leukoencephalopathy in a small number of patients.

Detailed analysis of this and subsequent studies in RA patients indicate that the B-cell depletion, which may depend on *FCGR3* genetic variants, is profound (<2%), with no major differences in infection rates between groups with the possible exception of lower respiratory tract infections. Repopulation occurs at a mean of 8 months after treatment, comprises immature IgD$^+$ CD38$^+$CD27$^-$CD5$^+$ B cells, and is associated with increased serum B cell–activating factor (BAFF) levels. Early relapse is associated with reconstitution of CD27$^+$ memory B cells. The effects on serum immunoglobulin levels are modest with levels remaining in the normal range, unless patients undergo repeated cycles of B-cell depletion. Selective and rapid decreases in pathogenic IgM, IgG, and IgA RF (~60%) and IgG anti-CCPs autoantibodies have been documented; these changes are more striking in rituximab responders. Antibody titers to tetanus toxoid or to pneumococcal capsular polysaccharides were only modestly affected (~25%). These changes are intriguing given that terminally differentiated plasma cells do not express CD20. One possibility is that germinal center and marginal zone B cells may be resistant to anti-CD20. B-cell depletion is surprisingly well tolerated; however, in contrast to other biological agents, it may induce long-lasting immunocompromise.

Future Prospects for Therapy

There remain unmet needs in the treatment of RA. Principal among these are the fact that until relatively recently, treatment has been considered lifelong for the majority of patients, imposing greater risk of toxicity and, as the immune system senesces, increased risk of infection or lymphoproliferative disease. There is little doubt that early treatment with tight control offers the best outcomes. Indeed, several synthetic and biological DMARDs are now being tested in at-risk subjects to establish whether they can delay or even prevent development of clinically apparent disease. A better appreciation of the profile of RA-specific autoantigens has prompted early- phase studies to establish the safety and tolerability of peptide immunotherapy delivered by autologous DCs. From an immunological perspective, there remains a pressing need to develop immunological tools or immune biomarkers that can redefine disease subsets and measure effector and regulatory cell subsets. This must be achieved with technology that is readily accessible to routine clinical laboratories and that uses methods that will inform disease activity states at a biological level. While such tools may provide better insights into disease pathogenesis, they can also be adapted to monitor the impact of therapeutic intervention, whether this turns out to be cell-based therapy or the application of novel immune modulators. It is possible that similar approaches to developing immune signatures could be used in the future to identify those ACPAs$^+$ arthralgia patients who have a genetic predisposition to RA and are at highest risk of developing the disease.

MULTIPLE-CHOICE QUESTIONS

1. Which of the following statements is correct regarding autoantibodies in rheumatoid arthritis (RA)?
   A. Antibodies to citrullinated peptides are highly specific for rheumatoid arthritis.
   B. Citrullination is found only in joint tissues.
   C. Citrullination requires the presence of the amino acid asparagine.
   D. Citrullination generates antigenic epitopes by posttranslational modification of pathogen-derived peptides.
   E. Antibodies to citrullinated peptides are generated after onset of disease.

2. Which of the following statements is correct regarding the shared epitope?
   A. The shared epitope refers to a common bacterial antigen.
   B. The shared epitope refers to a common viral antigen.
   C. Antibodies to the shared epitope are characteristic for RA.
   D. The shared epitope refers to a common sequence in a subset of major histocompatibility complex class II alleles.
   E. The shared epitope causes rheumatoid arthritis.

3. Which of the following characteristics are NOT typical features of individuals at high risk of developing RA?
   A. A family history of RA
   B. Low body mass index (BMI)
   C. Inflammatory joint pain
   D. A history of tobacco exposure
   E. Low alcohol intake

Juvenile Idiopathic Arthritis

Randy Q. Cron, Peter Weiser, Timothy Beukelman

Juvenile idiopathic arthritis (JIA) is a collection of conditions that manifest with chronic arthritis in childhood. By definition, JIA occurs prior to the 16th birthday (juvenile), has no known causes (idiopathic), and has evident chronic (>6 weeks' duration) swelling/inflammation of a joint or joints (arthritis).[1] The nomenclature and subcategorization of JIA have been published, with a second revision in 2004, partly in an attempt to unify the American (juvenile rheumatoid arthritis [JRA]) and European (juvenile chronic arthritis [JCA]) classification schemes.[1] Removal of the word "rheumatoid" was also important to distinguish these unique disorders from adult rheumatoid arthritis (RA) (Chapter 52). The new classification of JIA also includes the human leukocyte antigen (HLA)-B27–associated spondyloarthropathies (Chapter 57), which occur frequently during childhood (Table 53.1).

Because JIA is a diagnosis of exclusion, other causes of childhood chronic arthritis need to be ruled out. For example, sarcoidosis (Chapter 73), Sjögren disease (Chapter 54), systemic lupus erythematosus (SLE) (Chapter 51), Lyme disease (Chapter 28), dermatomyositis (Chapter 56), and a variety of vasculitides (Chapters 58 and 59) may all present as chronic arthritis in childhood. JIA, by definition, is idiopathic; however, chronic arthritis as part of inflammatory bowel disease (IBD) (Chapter 75) or associated with psoriasis (Chapter 64) is categorized under the JIA umbrella. When considering the seven categories of JIA together, the estimated prevalence of JIA is roughly 1 in 1000 children, with rates varying in different regions of the world, likely because of genetic risk factors and/or environmental triggers. Moreover, the relative rates of JIA categories vary in different regions of the world (*e.g.,* oligoarticular JIA is very common in Scandinavia, and enthesitis-related JIA is more typical in Latin America).

ETIOLOGY AND PATHOGENESIS

Genetic Contribution

Because JIA is an eclectic group of disorders with joint inflammation, is far less common than RA, and is classified into unique categories based largely on subjective clinical phenotypes, understanding its genetic causes is extremely difficult. Indeed, the relatively arbitrary distinction of having ≤4clinically arthritic joints to be considered as oligoarticular JIA is influenced by whether temporomandibular joint (TMJ) arthritis (or in essence any other suspected joint involvement) is screened for with magnetic resonance imaging (MRI) because clinical examination is neither sensitive nor specific for diagnosing TMJ arthritis.[2] Distinctions based on the types and location of joints manifesting arthritis may prove useful in identifying more homogeneous subtypes. Thus the criteria will likely continue to evolve and benefit from more precise clinical, laboratory, and genetic distinctions. One such suggested reclassification of JIA categories is based on shared similarities among children with JIA who are positive for antinuclear antibody (ANA)[3] regardless of total joint count, and a recent proposal used probabilistic principal component analysis of a large set of biological and clinical data to subdivide patients with JIA.[4] Moreover, there have been several attempts to characterize the genetics of the JIA categories by using a variety of approaches.[5]

Polygenic Disorder

Like most autoimmune conditions, JIA is a polygenic disorder with ≥20 potential genes contributing to the phenotypes of chronic arthritis presenting during childhood. An exception is the systemic JIA (sJIA) category, which resembles an autoinflammatory disorder rather than a solely autoimmune process.[6] Unlike autoimmunity, which is believed to be the result of an imperfect adaptive immune system, autoinflammatory conditions are thought to result from genetic perturbations in the innate immune response. Many autoinflammatory recurrent fever syndromes have been identified as resulting from single gene defects, such as pyrin in familial Mediterranean fever (FMF), and tumor necrosis factor (TNF) receptor in *TNFR1*-associated periodic syndrome (TRAPS) (Chapter 60).[6] Whether sJIA is the result of a single gene defect or is one of many potential single gene defects in the same immune pathway is currently unknown. However, a common complication of sJIA is the life-threatening condition of macrophage activation syndrome (MAS), which resembles familial hemophagocytic lymphohistiocytosis (fHLH) (Fig. 53.1). MAS may be present in ≈50% of children with sJIA in either an overt or occult/subclinical fashion.[7] Recently, genetic polymorphisms and heterozygous (single copy) mutations in genes associated with fHLH when present as homozygous defects have been identified in children with sJIA and overt MAS.[7] Protein products of these genes, including perforin 1 and MUNC 13-4, are critical in the pathway mediating cytolysis by CD8 T cells and natural killer (NK) cells (Chapter 17). This cytolysis is crucial to the ability to shut down an immune response following control of infection. Defects in this pathway can result in a hyperinflammatory state (cytokine storm) leading to pancytopenia, coagulopathy, and multisystem organ failure.[7] The most common condition resulting in MAS during childhood is sJIA. Therefore sJIA may be genetically related to fHLH but associated with

TABLE 53.1 Clinical and Laboratory Features of the Juvenile Idiopathic Arthritis (JIA) Categories

	JIA					
Classifications	**Former Juvenile Rheumatoid Arthritis (JRA)**				**Spondyloarthropathy**	
JIA categories/ features	Systemic	RF^- polyarticular	RF^+ polyarticular	Oligoarticular (persistent & extended)	Psoriatic (early and late onset)	Enthesitis-related arthritis (ERA) (including ankylosing spondylitis (AS) and inflammatory bowel disease [IBD])
Human leukocyte antigen (HLA)	DRB1*11	DRB1*08	DRB1*04	A2	DRB1*01	B27
Gender	Equal	$F \gg M$	$F \gg M$	$F \gg M$	$F > M$	$M \gg F$
Age at onset	Peak 2 years	Dual peaks	Teenage	1–3 years	Dual peaks	Teenage
Antinuclear antibody (ANA)	Rare	Yes	Yes	Yes	Yes	Rare
Uveitis	Rare	Yes	Yes	Yes	Yes	Non-silent
Temporomandibular joint (TMJ)	Yes	Yes	Yes	Yes	Yes	Yes
Enthesitis	No	No	No	No	Older age	Yes
Arthritis	Erosive	Symmetric	Erosive	Mixed	Dactylitis	Axial

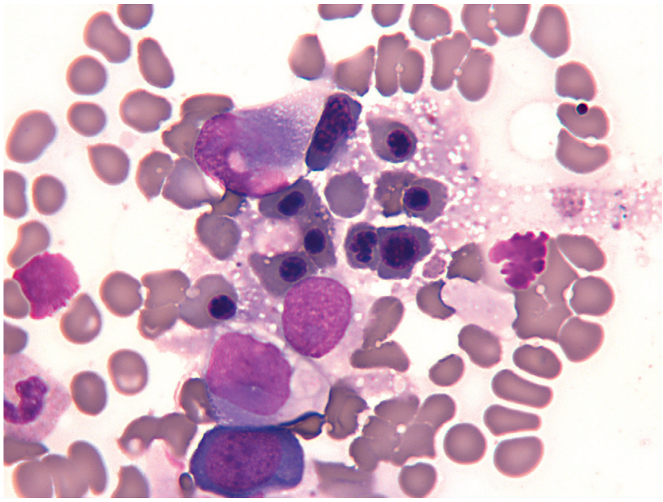

FIG 53.1 **Hemophagocytosis as Part of Macrophage Activation Syndrome (MAS).** A centrally located, vacuolated histiocyte is pictured engulfing numerous nucleated immune cells and non-nucleated mature red blood cells. Wright stain at ×198 magnification. (Courtesy of Dr. David Kelly.)

heterozygous, rather than homozygous, mutations in genes critical for cytolysis.[7]

HLA Associations

For all other JIA categories, polygenic influences, including the major histocompatibility complex (MHC), contribute to disease pathology. The MHC is complex and densely packed (>200 genes) with immune-associated genes (Chapter 5). The MHC is also the most polymorphic region of the human genome and gives rise to MHC class I and class II genes, complement proteins, TNF, and others. The critical role of MHC proteins in preventing autoimmunity by shaping the T-cell repertoire (Chapter 8) likely explains why the MHC is the most consistently and strongly associated genetic locus for most JIA categories. However, weak MHC associations and lack of gender predilection in the development of sJIA are additional arguments to consider sJIA as autoinflammatory rather than autoimmune.

In contrast, enthesitis-related arthritis (ERA) and psoriatic JIA share one of the strongest known MHC associations, HLA-B27, for any described autoimmune disorder. HLA-B27 is present in 70–90% of Caucasian children with ERA. Inheritance of ERA follows an autosomal dominant pattern and is the only JIA category likely to have similarly afflicted first-degree relatives. The pathophysiological explanation for the association of HLA-B27 remains unknown, but hypotheses vary from molecular mimicry of pathogens presented by HLA-B27 (Chapter 50) to the unfolded protein response.[8] The remaining JIA categories have all been linked to various other MHC proteins to lesser degrees (see Table 53.1).

Non-HLA Associations

Genes outside of the MHC have also been linked to developing JIA. Genetic approaches have highlighted the importance of genetic differences in the development of JIA, but at most, 11% of the contribution can be linked to the MHC.[5] Recent developments in high-throughput genetic sequencing combined with the identification of densely present restriction fragment length polymorphisms (RFLPs) throughout the human genome have allowed for powerful new genetic approaches. These include genome-wide association studies (GWAS) designed to identify genes associated with a variety of disorders, including autoimmune diseases, such as JIA.[9] To date, several genes have been reported to be associated with JIA.[5]

Strong evidence that genetic factors contribute to JIA susceptibility include twin and family studies. Data from a JIA national registry revealed that monozygotic twin pairs have a higher-than-expected proportion of twins with JIA. Moreover, siblings of children with JIA have as high as a 30-fold increased risk of JIA compared with the general population. Interestingly, siblings with JIA typically share the same JIA category, age of onset, and disease course.[5] Polymorphisms in MHC class II genes have been estimated to account for <20% of the recurrence risk of JIA in siblings and thus support the concept that JIA is a complex genetic trait. JIA likely shares general or common autoimmunity gene risk factors with many autoimmune disorders but may also be influenced by specific JIA risk-associated genes.[9]

Using linkage and association studies, researchers have identified a variety of potentially JIA-associated genes. However, outside of the HLA genes, only a small percentage of these genes have been independently confirmed by other investigators. A few of the independently confirmed JIA-associated genes/gene products include *PTPN22* (a phosphatase involved in inhibition of T-cell activation), *WISP3* (a signaling protein), interleukin-1α (a proinflammatory cytokine), TNF (another proinflammatory cytokine), macrophage migratory inhibitory factor (MIF), and *SLC11A1* (a resistance factor to intracellular pathogens in macrophages).[5] Thus gene products linked to both innate and adaptive immune responses likely contribute to JIA disease susceptibility. Ongoing GWAS may help validate the importance of these genes and may identify other candidate gene risk factors for JIA in the near future. Recently, epigenetic (modifications to DNA nucleotides rather than changes in the DNA sequence) risk factors that confer susceptibility to JIA are beginning to be explored.[10]

ENVIRONMENTAL FACTORS

In addition to genetic factors, there are likely a variety of environmental triggers for developing JIA in genetically susceptible hosts. A number of infectious agents have been explored as risk factors for development of JIA. Perhaps two of the best studied have been parvovirus and rubella virus infections. However, replication of these associations has been difficult. In addition, some scientists have suggested that heat shock proteins, resulting from cells undergoing environmental stress, may contribute to the development of JIA.[11] There is also a clear link between gut pathogens and potentially commensal organisms (gut microbiome) and the development of HLA-B27–associated spondyloarthropathies.[12] Last, prior to the identification of *Borrelia* as a cause of childhood arthritis, Lyme disease associated arthritis was difficult to distinguish from oligoarticular JIA.[13] Perhaps because there a variety of potential environmental triggers for JIA, combined with the number of different JIA categories, no single environmental trigger has been conclusively identified as contributing to the development of JIA.

IMMUNE ABNORMALITIES

Autoantibodies

As JIA is considered an autoimmune disease, except for sJIA as discussed earlier, there have been a variety of explorations into the role of various components of the immune system involved in JIA pathogenesis. The importance of the immune system in JIA pathology is highlighted by the increased incidence of childhood chronic arthritis among children with various immunodeficiencies. For example, children with immunoglobulin A (IgA) deficiency are at increased risk of developing chronic arthritis. In contrast, the presence of specific autoantibodies is associated with various forms of JIA. ANAs are present in up to 40% of patients with JIA, particularly those with oligoarticular JIA and are associated with silent uveitis (Chapter 74).[14] Similarly, antibodies to the nuclear oncoprotein DEK have been associated with uveitis as well as joint inflammation in children with JIA. IgM rheumatoid factor (RF) is present in a smaller subset of children with polyarticular JIA and is associated with a more aggressive/erosive form of arthritis as in adults with rheumatoid factor–positive (RF$^+$) RA (Chapter 52).[1] More recently, identification of anti–cyclic citrullinated peptide (CCP) antibodies have been found in a partially overlapping subset of children with RF$^+$ poly-JIA.[15] Thus a variety of autoantibodies are associated with JIA.

T-Helper Cells

T lymphocytes are also thought to play a major role in the development of JIA as evidenced by their relative predominance among mononuclear cells in synovial fluid of chronically inflamed joints in children with JIA. CD4 T-helper (Th) cells have been categorized into a variety of cytokine-producing subsets (Chapter 16). CD4 Th1 cells characterized by the production of interferon-γ (IFN-γ) have been identified in chronically inflamed joints in children with JIA, whereas IL-4–producing Th2 CD4 T cells are more commonly involved in the joints in oligoarticular JIA (generally less aggressive arthritis) than in polyarticular JIA. More recently, two relatively newly described CD4 Th subsets, regulatory T cells (Tregs) and Th17 cells, are being examined as potential players in JIA pathology.

CD4$^+$, CD25^{high} Tregs are characterized by the transcription factor, FoxP3, and by the ability to suppress immune activation (Chapter 18).[16] The ability of Tregs to suppress other T cells likely occurs by both cell-contact dependent (through the surface protein cytotoxic T lymphocyte antigen-4 [CTLA-4]) and independent (via suppressive cytokines) mechanisms.[16] Tregs secrete the antiinflammatory cytokines, IL-10 and transforming growth factor-β (TGF-β). Th17 cells, characterized by the transcription factor, retinoid orphan receptor (ROR)γT, produce the proinflammatory cytokine, IL-17.[17] IL-17 is thought to contribute to a variety of autoimmune disorders, including JIA. The balance between these two juxtaposed Th subsets may determine whether autoimmunity develops (Th17-dominant) or a state of immune tolerance to self (Chapter 12) persists (Treg-dominant). Indeed, recent studies have identified a predominance of Th17 cells and associated proinflammatory cytokines in the inflamed joints of children with JIA.[17] Thus a balance of proinflammatory cytokines and suppressive cytokines may dictate the expression of autoimmunity in the form of JIA.

Cytokines

Cytokines (Chapter 9), and particularly their inhibition, have taken a prominent status in the pathology and treatment of chronic arthritis, including JIA. The bench-to-bedside translation of anti-TNF therapy to the treatment of chronic arthritis has revolutionized the care of adults with chronic arthritis, as well as children with JIA. Inhibition of this proinflammatory cytokine in the circulation (via specific monoclonal antibodies [mAb] or receptor fusion proteins) rapidly and effectively treats most forms of JIA.[1] The one exception is sJIA, which may or may not respond to anti-TNF treatment. However, other proinflammatory cytokines, including IL-1, -6, and -18, are thought to be central to sJIA pathogenesis.[1] Indeed, serum from sJIA patients was shown to induce transcription of a variety of innate immunity genes, including IL-1, in normal peripheral blood mononuclear cells. Fortunately, novel therapies that target either IL-1 or IL-6 have proven highly successful in treating even the most severe forms of sJIA, including associated macrophage activation syndrome (MAS).[1,7]

Macrophage Activation Syndrome

The sometimes fatal complication MAS is most commonly seen in sJIA among rheumatic diseases. Clinically, MAS resembles many features of a sJIA disease flare-up, and it has been suggested

KEY CONCEPTS

Macrophage Activation Syndrome (MAS)

- MAS is present in up to 50% of children with systemic juvenile idiopathic arthritis (sJIA) in a subclinical or overt (10%) form.
- MAS manifests as fever, liver dysfunction, pancytopenia, central nervous system disturbance, hyperferritinemia, hemophagocytosis, and coagulopathy.
- MAS resembles hemophagocytic lymphohistiocytosis (HLH) and is thought to result from defects in perforin-mediated cytolysis by CD8 T cells and natural killer (NK) cells.
- Patients with sJIA and MAS have been noted to have NK-cell defects and mutations in perforin-1 and MUNC13-4 cytolytic pathway genes.
- MAS can be fatal if not recognized and treated early. Mainstays of therapy include high-dose corticosteroids and cyclosporine.
- Recently, interleukin-1 (IL-1) blockade with biological therapies has been found to be quickly and dramatically beneficial in treating MAS associated with sJIA.

that MAS may be inherent to sJIA disease pathology in up to half of all patients with sJIA.[7] MAS is likely part of the spectrum of HLH disorders. Primary HLH, or fHLH, typically presents in infancy following infection and results from homozygous mutations in genes involved in the cytolytic pathway employed by NK cells and CD8 T cells. Recent evidence suggests that patients with sJIA who have MAS have heterozygous defects in these same cytolytic pathway genes.[18] MAS can be triggered by a variety of infectious organisms, particularly members of the herpes virus family, but the precise role of infectious triggers of MAS in children with sJIA remains unknown. Nevertheless, the inability to effectively shut down an immune response via cytolytic mechanisms results in a "storm" of proinflammatory cytokines, such as IL-1, IL-6, IL-18, TNF, and IFN-γ. Mouse models of MAS/HLH have suggested that IFN-γ is the pivotal cytokine in MAS. In practical terms, inhibition of IL-1, and potentially of IL-6, has proven rather effective at treating MAS in children with sJIA.[1,7,18] It is quite remarkable how dampening of one critical cytokine can help restore the immune imbalance of multiple proinflammatory cytokines and rapidly reverse the life-threatening clinical scenario of MAS.

JIA CLINICAL SUBTYPES

As already mentioned, JIA is a group of chronic inflammatory joint diseases, which last for at least 6 weeks and commence prior to the age of 16 years with no identifiable cause. There is heterogeneity of clinical presentation and progression of the various subtypes, which is largely addressed by the International League Against Rheumatism (ILAR) classification schema (see Table 53.1). Nevertheless, as more information about genetic factors, response to medication, and subsequent outcomes becomes available from multicenter studies, revisiting the classification in the near future seems inevitable. A recent elegant report has suggested five distinct groups of patients categorized on the basis of clinical disease trajectories, all with subsets different from those defined by the ILAR classification.[4]

The current classification of JIA relies heavily on the number of the joints involved (≤4in oligoarticular JIA; ≥5 in polyarticular JIA, with or without the presence of RF).[1] Other categories of JIA are also classified on the basis of associated symptoms and signs, including fever, rash, and laboratory indicators of inflammation in sJIA, or associated diseases, such as psoriasis. There is a separate JIA category affecting boys more than girls—ERA, with inflammation of the entheses, attachments of the tendons, and ligaments to bone (see Table 53.1).[8] An important finding of recent years is that imaging (MRI and, in certain cases, ultrasonography) can identify ongoing inflammation in clinically asymptomatic joints. This has led to screening for TMJ inflammation primarily with MRI, as arthritis of this joint is frequently clinically silent but capable of resulting in facial dysmorphism from micrognathia in all JIA categories, including oligoarticular JIA.[2]

Oligoarticular JIA

Oligoarticular JIA is likely the most common category of JIA, affecting children who have 1–4 joints inflamed, most commonly knees, ankles, the TMJ, and fingers.[1] The archetype of this group is a preschool-aged, blonde-haired, blue-eyed girl who limps and has swollen knees. The diagnosis of arthritis may be delayed, as it is often painless. Because of this, by the time she is seen in the medical office, she may already have developed bony hypertrophy and limb length discrepancy, as chronic articular inflammation stimulates the osteoblasts of the nearby growth plates. In addition, there is often notable muscle wasting around the arthritic joint that can last into adulthood. The oligoarticular JIA category has the highest percentage of positive ANA blood tests and associated potentially damaging silent uveitis.[14] Monoarticular involvement calls for a careful differential diagnosis. JIA rarely presents with isolated hip involvement; toxic synovitis, septic hip, and malignancy all need to be considered. Oligoarticular JIA is also quite uncommon in middle and high school aged children, where the diagnosis of reactive arthritis, IBD-related arthritis, and Lyme disease should be entertained. The ILAR classification has a separate sub-category for children who develop additional joint involvement after the first 6 months based on clinical presentation, extended oligoarticular JIA,[1] which might be a variant of the RF-negative polyarticular category. Wrist involvement is considered to be a bad prognostic factor, as is the extended oligoarticular phenotype, and elevated laboratory indicators of inflammation.

Polyarticular JIA

Arthritis of ≥5 joints includes two main JIA categories (see Table 53.1) based on the presence of serum RF, an IgM antibody against the IgG Fc receptor.

RF-positive serum on two occasions at least 3 months apart is required for a child to be diagnosed with RF$^+$ polyarticular JIA. Joint involvement is typically bilateral and symmetrical, involving the small joints of hands and feet.[1] However, large joints and cervical involvement are often present. RF$^+$ polyarticular JIA usually presents in adolescent girls and is considered a form of early-onset adult RA.[1] It is a relatively infrequent category of JIA with <5 % of all patients with JIA classified in this category. Antibodies to CCP are much less common in children with polyarticular JIA than in adults,[15] but affected children usually have active arthritis for many years. The presence of RF predicts more destructive/erosive disease calling for early aggressive therapy. As in adult RA, arthritis of the wrists and fingers can lead to ulnar deviation and boutonniere and swan neck deformities. Destructive TMJ involvement is also common.[2] Similar to adult RA, RF$^+$ polyarticular JIA in children commonly has extraarticular manifestations, such as low-grade fever and occasionally rheumatoid nodules over bony surfaces.

RF-negative polyarticular JIA usually presents as asymmetrical involvement of the large joints, mostly knees, wrists, and ankles.

As in psoriatic JIA, small joint involvement tends to occur later in life. Another similarity between psoriatic JIA and RF^{-} polyarticular JIA is the bimodal distribution in preschool children and early adolescent patients.[1] There is more frequent silent uveitis in the former group, and this form of JIA is often difficult to distinguish from ERA in the latter. TMJ inflammation occurs frequently, leading to condylar damage and facial dysmorphism.[2]

Psoriatic Arthritis

Arthritis with concurrent psoriasis, or arthritis with two of three factors—dactylitis, psoriatic nail changes, or family history of a first-degree relative with psoriasis—comprises a separate category of JIA. There seems to be a bimodal distribution of age at onset for psoriatic JIA.[19] Preschool-aged children have mostly large joint involvement like those in the oligoarticular category but may also have dactylitis, whereas middle school–aged patients have JIA that resembles ERA with enthesitis, sacroiliac joint involvement (albeit milder), and even spondylitis.[8] In general, there is asymmetrical involvement of the joints, and if untreated, it will progress to polyarticular joint disease. Since up to 50% of the patients develop psoriatic skin findings several years after arthritis presentation, it is often difficult to diagnose this condition at onset. It is important to carefully examine children with JIA for dactylitis (tenosynovitis causing swelling of the digit beyond the joint capsule) and nail pits and onycholysis. Psoriatic JIA seems to be more resistant to therapy, and approximately 40% of children have active disease into adulthood while on medications. Insidious onset of anterior uveitis is more typical for the younger age group, whereas those with enthesitis have JIA that resembles the adult type of psoriatic arthritis with an associated HLA-B27 genotype and chronic symptomatic, often painful, eye disease (see Table 53.1).

Enthesitis-Related Arthritis

ERA affects boys more than girls[1] and may sometimes be a manifestation of IBD. Entheses are the attachments of the tendons, ligaments, or joint capsules to bone. These can be tender even in healthy children, but usually ≥3 tender entheses are associated with disease (see Table 53.1). ERA often occurs in boys 8 years of age and older.[1,8] They typically complain of joint pain related to playing sports, but there is also morning stiffness and pain that gets better during the day and worsens toward the end of the day or after engaging in a lot of activities. Many consider ERA a potential prelude to ankylosing spondylitis (Chapter 57), a HLA-B27–associated inflammatory condition resulting in irreversible fusion of the vertebrae. Recent therapeutic efforts are focusing on preventing the calcifying hypercorrection of inflamed vertebral edges using TNF blockade. Outcomes are still under investigation but appear promising with early treatment.

Systemic JIA

Approximately 10% of children with chronic arthritis belong to the sJIA category, also known as *Still disease.* The peak incidence of sJIA is ages 1–5 years, but it can present in adulthood. The ILAR criteria to classify sJIA require fever for 2 weeks, with at least three episodes of daily spiking (quotidian) fever, with at least one of the following: fleeting pink macular rash, arthritis, lymphadenopathy, and hepatosplenomegaly.[1] When febrile, children appear rather ill, and the rash is more prominent and can be evoked by contact (Koebner phenomenon). Typically, the fever subsides, and children are visibly better in the morning hours. High levels of indicators of systemic inflammation are typical at onset and may subside later in the disease. Arthritis is often very aggressive and frequently involves wrists, ankles, and knees but also causes ankylosis of the hip and neck leading to long-term damage and gait abnormalities. Occasionally, joint involvement begins months after fever onset, making sJIA diagnosis more difficult. The initial presentation mimics those of infections and malignancies, and this has to be taken into consideration, as sJIA is a diagnosis of exclusion. Fifty percent of children may develop (only 10% clinically overt) MAS, described previously.[7]

Laboratory Evaluation

There is no one laboratory indicator that will establish or rule out chronic arthritis *per se.* The complete blood count (CBC) is largely normal in oligoarticular involvement, as is the erythrocyte sedimentation rate (ESR). White blood cells (WBCs) are highly elevated in sJIA but are mostly within normal limits in other groups. Anemia of chronic disease presents as normocytic and normochromic and is often found in polyarticular involvement. In those cases, the ESR can also be elevated. Intermittent joint effusion of a single large joint with an elevated ESR necessitates further evaluation, and IBD should be considered, especially if there is a low serum albumin level and/or growth delay. Of note, elevated ESR on presentation predicts a worse outcome for those with the oligoarticular subtype. The platelet count, as a marker of inflammation, can be elevated in polyarticular disease and substantially so in sJIA.

Liver function tests are used for monitoring certain disease modifying antirheumatic drugs (DMARDs), such as methotrexate and leflunomide. They can be elevated as a result of prolonged, and frequently concomitant, use of nonsteroidal antiinflammatory drugs (NSAIDs).

As mentioned above, in 10% of patients, sJIA can progress to overt MAS. Ferritin, an acute-phase reactant, is a very sensitive indicator of this condition. A sudden drop of at least two cell lines in the CBC, a rising cross-reactive protein (CRP) level with decreasing ESR, elevated liver transaminases, prolonged prothrombin or partial thromboplastin times, high D-dimer levels, elevated triglycerides, and low fibrinogen should all alert caregivers about the likelihood of MAS in a child with sJIA.[7]

Although 75–85% of adult patients with RA have either a RF or CCP antibodies, <5% of patients with JIA have the RF, and those are mostly patients with early-onset RA, often teenage girls with symmetrical small joint involvement. Another rather frequently ordered test is the serum ANA titer. Similar to the RF, ANA is not suitable for screening, as it is of no diagnostic utility in either making or excluding a diagnosis of JIA.[20] ANA serves as a prognostic factor by identifying patients already diagnosed with JIA who have the highest risk for developing uveitis.[3,14] In addition, ANA levels may alert the clinician to the possibility of juvenile Sjögren disease or SLE being the etiology for the chronic arthritis.

The prevalence of the HLA-B27 antigen is 8% in the general Caucasian population but nearly 90% in the ankylosing spondylitis group.[8] HLA-B27 is useful to predict axial involvement in ERA, psoriatic JIA, and IBD-related arthritis but should be evaluated in patients with clinically established arthritis and/or enthesitis, rather than as a routine screening test during a workup for back pain.

Additional laboratory indicators may be helpful. Elevated serum lactate dehydrogenase and uric acid levels may indicate malignancy. Elevated angiotensin converting enzyme (ACE) and lysozyme levels are useful when considering sarcoidosis as the etiology of childhood arthritis and uveitis in early-onset sarcoidosis cases, but noncaseating granulomas seen on biopsy are much more revealing. As for imaging techniques, radiography can be helpful in ruling out structural changes resulting from disease processes other than arthritic disease. Nevertheless, periarticular osteopenia is commonly seen around an inflamed joint. The clinical presentation usually precedes the development of bony erosions, but sclerosis of the sacroiliac joint may indicate axial involvement in patients with ERA. The role of ultrasonography for diagnosis and monitoring of disease progression in pediatric patients is promising, but further establishment of normative data is still required. MRI, with and without intravenous contrast, may help identify synovitis, but even this imaging modality can sometimes yield false-positive results in certain joints in otherwise healthy children.[8,21,22]

DIFFERENTIAL DIAGNOSIS

A wide variety of conditions can mimic the symptoms and signs of JIA. Although both acute and chronic arthritis may present with joint pain, tenderness, swelling, and warmth, a single acutely involved joint at onset should be considered septic until proven otherwise. Septic arthritis frequently has an erythematous discoloration of skin, whereas JIA does not. Prompt evaluation with arthrocentesis is necessary, especially in indeterminate cases. Infection of the joint may lead not only to rapid destruction of the joint but also to systemic dissemination of infection. Specifically, *Kingella* species should be considered in painful monoarticular cases of young children when symptoms have sudden onset without prolonged morning stiffness.

Parainfectious arthritis, often resulting from viral disease, is usually short-lived and typically requires only NSAID treatment. In contrast, Lyme disease is characterized by a chronic extensively swollen joint(s), commonly the knee.[13] It appears several weeks to months after the usually unnoticed tick bite and should be considered in areas of high incidence (*e.g.,* northeastern United States). There are a few diseases associated with migratory arthritis, including malignancy, gonococcal arthritis, and rheumatic fever arthritis, the last having a typically very tender, red, hot joint persisting in each location for a couple of hours before moving to another.

As sJIA is a diagnosis by exclusion, multiple other etiologies of systemic inflammation should be considered. Fever and elevated WBCs, platelets, and ESR may accompany polyarteritis nodosa, Kawasaki disease, Henoch-Schönlein purpura, and other vasculitides. Ehrlichiosis and recurrent fever syndromes (*e.g.,* familial Mediterranean fever, TNF receptor–associated periodic fever syndrome) may also manifest as systemic inflammation, arthralgias, and rashes. A typically nonerosive symmetric arthritis may occur in SLE, often with cytopenias. Arthritis is also seen in related diseases (*e.g.,* Sjögren syndrome, mixed connective tissue disease [MCTD]), and evidence of antibodies to extractable nuclear antigens are common in SLE (anti-Smith, anti–double-stranded DNA) and MCTD (anti–ribonuclear protein [RNP]).

Patients presenting with joint pain only, without associated swelling or morning stiffness, most commonly have overuse syndromes or benign hypermobility syndrome.[23] Little league shoulder and elbow are rather common in middle school–aged baseball players; wrist pain occurs in gymnasts frequently. Pain in the hip, without morning stiffness, may indicate Legg-Calve-Perthes disease or slipped capital femoral epiphysis. Relentless knee pain without improvement in teenagers could be caused by osteochondritis dissecans. Other common causes of teenage knee pain include Osgood-Schlatter disease and patellofemoral syndrome.

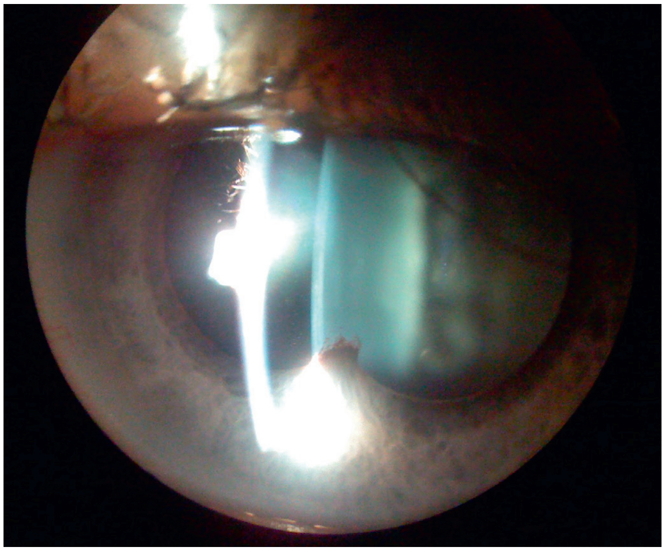

FIG 53.2 Posterior synechia, a complication of chronic anterior uveitis, is associated with several categories of juvenile idiopathic arthritis (JIA). The irregularities of the inner margins of the iris reflect fibrous adhesions between the iris and lens capsule. (Courtesy of Dr. Scott Olitsky.)

Clinically Silent Complications

There are two common findings that present insidiously during the course of JIA and yet can cause major damage/morbidity—uveitis and TMJ arthritis. Uveitis is a relatively common complication of JIA with potentially long-term morbidity. Risk factors for uveitis among patients with JIA include young age of onset, positivity for ANA, oligoarticular disease, and female sex.[14] It usually presents as iridocyclitis, but the choroid may also be affected. Although extremely rare in sJIA, approximately 20% of patients with oligoarticular JIA and 5% of patients with polyarticular JIA develop eye inflammation.[14] Some children with psoriatic JIA are also at risk of developing silent uveitis, especially in the ANA-positive subgroup.[19] Uveitis may lead to a great deal of morbidity, including cataracts, increased intraocular pressure, band keratopathy, and posterior synechiae (Fig. 53.2), with decreased vision developing in up to 40%.[14] The danger of most JIA-associated uveitis is its asymptomatic presentation, with the exception of symptomatic uveitis in children with ERA. Considering that the highest prevalence is in patients with oligoarticular JIA, which is most common in preschool and younger children, it is not surprising that many of the cases go unnoticed. A routine ophthalmological examination may fail to detect uveitis, and children need to have a formal slit-lamp examination to identify inflammatory cells.[14] The most common presenting signs are synechiae (an irregular iris border resulting from adhesions to the lens), hypopyon, and band keratopathy (see Fig. 53.2). Uveitis may develop many months or years after joint symptoms, and therefore close follow-up is warranted. ANA positivity and young age are associated with increased incidence; thus ANA-positive children with oligoarticular JIA need to be screened the most often, but those in other categories should be followed up on a set schedule as well.[14] Failure to do so and missed eye involvement may lead to the occurrence of cataracts, glaucoma, impaired vision, and even blindness.

KEY CONCEPTS

Temporomandibular Joint (TMJ) Arthritis

- TMJ arthritis is extremely common, present in up to 80% of children with juvenile idiopathic arthritis (JIA). It is typically asymptomatic and thus requires early screening with magnetic resonance imaging (MRI) with contrast.
- TMJ arthritis is often active despite therapy with disease-modifying antirheumatic drugs (DMARDs) and biologicals (*e.g.,* methotrexate plus tumor necrosis factor [TNF] inhibitors) and thus treatment with intraarticular long-acting corticosteroids or TNF inhibitors may help prevent mandibular growth damage and associated micrognathia and facial dysmorphology.

Another frequently asymptomatic complication of JIA is TMJ arthritis. TMJ arthritis in children with JIA has been recognized increasingly in recent years as a joint inflammation leading to silent destruction and facial deformity despite systemic therapy.[2] TMJ arthritis is quite common, with 40–80% of all patients with JIA patients affected.[2] The overall true prevalence is likely closer to the higher range, since not all children with JIA receive TMJ MRI screening, which frequently reveals synovial thickening (Fig. 53.3) at disease onset, and premicrognathic arthritis may be missed.[2,22] The highest rates of TMJ arthritis have been found in the extended oligoarticular JIA and RF-negative polyarticular JIA groups, as well as in children with upper extremity and neck involvement, as well as an elevated ESR.[2] Currently, intraarticular corticosteroid injection seems to be beneficial in certain cases, whereas TMJ arthritis often develops despite systemic use of methotrexate and TNF inhibitors.[2] TMJ arthritis needs to be recognized early in children with JIA so that it can be treated prior to growth disturbance.

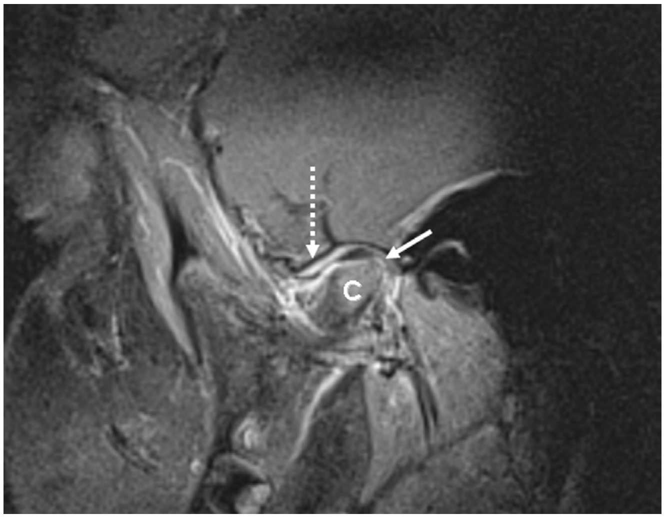

FIG 53.3 Acute and Chronic Temporomandibular Jaw (TMJ) Arthritis in a Child With Juvenile Idiopathic Arthritis (JIA). Synovial thickening and enhancement (long dashed arrow) and mandibular condyle ("C") flattening with contour irregularity/erosion (short arrow) are noted in this parasagittal postcontrast T1-weighted magnetic resonance imaging (MRI) image. TREATMENT

Overview

Despite significant advances in the understanding of the pathogenesis of JIA, there are currently no curative treatments. JIA frequently persists into adulthood and may result in significant morbidity, including physical disability. The objective of treatment is to prevent disability and preserve normal growth and development while providing relief of symptoms and improved quality of life by controlling the inflammatory process.[1]

Over the past 15 years, remarkable advances have been made in the treatment of JIA.[1] Chief among these advances was the advent of targeted biological therapeutic agents (Table 53.2) (Chapter 89). These agents have been shown to be quite beneficial against active disease and are generally well tolerated.[1] The early initiation of biological therapeutic agents may, in fact, alter and improve the subsequent disease course.[1] These new breakthroughs have prompted pediatric rheumatologists to "invert the treatment pyramid," that is, to rapidly incorporate more effective therapeutic agents instead of slowly progressing to them in a stepwise fashion.[1]

THERAPEUTIC PRINCIPLES

Early Aggressive Therapy

- Accumulating evidence suggests that early aggressive therapy that includes targeted biological agents near the time of clinical diagnosis (during the "window of opportunity") may improve the future disease course.

In response to the growing number of treatment options for JIA and the advent of the biological therapeutics, the American College of Rheumatology (ACR) issued Recommendations for the Treatment of JIA in 2011.[24] These recommendations were developed by using a rigorous methodology to produce evidence-based and consensus-based guidance that reflected the current state of the field. The guidelines were updated in 2013 to include advances in the treatment of sJIA.[25]

With new and effective therapies continuing to be introduced to the therapeutic armamentarium, treatment goals have become elevated and more stringent. The current goal is to achieve a status of clinically inactive disease,[26] that is, the absence of any significant signs or symptoms of active arthritis. Although currently this is not possible for all children, until that becomes a reality, curative therapy for JIA (achievement of inactive disease status) for as many children as possible remains the goal.

Recent advances in the treatment of adults with inflammatory arthritis have elucidated some differences in the effectiveness of specific biological agents for specific forms of arthritis. For example, many non-TNF inhibitor biologicals, such as abatacept, rituximab, and tocilizumab, are highly effective in the treatment of RA but are far less effective in the treatment of ankylosing spondylitis. In contrast, some of the more recently introduced biological agents, such as the IL-17 inhibitor secukinumab, appear effective against ankylosing spondylitis but are likely less effective for RA.[27]

Despite these recent advances, the treatment of JIA is not currently strongly influenced by the distinct categories of JIA, with the exception of sJIA. For example, there are no specific therapies currently approved for the treatment of children with psoriatic arthritis as opposed to RF-negative polyarthritis. Accordingly, the discussion of treatment in this chapter will not detail all categories of JIA but will focus rather on the "treatment groups" as defined

TABLE 53.2 Biological Therapeutic Agents Used in the Treatment of Juvenile Idiopathic Arthritis (JIA)

Biological Target	Name	Structure	Frequency of Administration	Route of Administration
Tumor necrosis factor (TNF)	Etanercept	TNF receptor-immunoglobulin G (IgG) fusion protein	Twice weekly to weekly	Subcutaneous (SQ) injection
	Infliximab	Monoclonal antibody (chimeric)	Every 4–8 weeks	Intravenous (IV) infusion
	Adalimumab	Monoclonal antibody (humanized)	Every 1–2 weeks	SQ injection
	Golimumab	Monoclonal antibody (humanized)	Every 4 weeks Every 8 weeks	SQ injection IV infusion
	Certolizumab pegol	Monoclonal antibody (humanized and PEGylated)	Every 2 weeks	SQ injection
CD80/86	Abatacept	Cytotoxic T lymphocyte antigen-4 (CTLA-4–IgG fusion protein	Every 4 weeks Weekly	IV infusion SQ injection
Interleukin-1 (IL-1)	Anakinra	Receptor antagonist	Daily	SQ injection
	Canakinumab	Monoclonal antibody (humanized)	Every 8 weeks	SQ injection
	Rilonacept	Receptor-fusion protein	Weekly	SQ injection
IL-6 receptor	Tocilizumab	Monoclonal antibody (humanized)	Every 2–4 weeks Every 1–2 weeks	IV infusion SQ injection
CD20^{+} B cells	Rituximab	Monoclonal antibody	2 infusions 2 weeks apart, repeat every 6 months	IV infusion
IL-12 and IL-23	Ustekinumab	Monoclonal antibody	Every 12 weeks	SQ injection
IL-17A	Secukinumab	Monoclonal antibody	Every 4 weeks	SQ injection

by the 2011 ACR Recommendations for JIA treatment.[24] As our knowledge about pathophysiology and response to treatment continues to expand, differential therapeutic approaches for the disparate JIA phenotypes are eagerly anticipated.

Nonsteroidal Antiinflammatory Drugs

NSAIDs formed the foundation of the treatment of JIA for decades, and numerous NSAIDs have been shown to have beneficial effects. In the absence of significant numbers of head-to-head trials, it is believed that in general all NSAIDs are similarly effective,[1] although indomethacin is considered by some to be the most effective NSAID (especially in sJIA). One NSAID may be found to be more effective than another for a particular individual child.

In general, NSAIDs are not considered to be disease-modifying agents, that is, they are not felt to slow the progression of disease or prevent the appearance of radiographic damage. For this reason, monotherapy with NSAIDs initially began to decline with the advent of agents, such as methotrexate, that have been shown to modify the disease process. NSAIDs are frequently used for symptomatic relief, but most children who require daily chronic use of NSAIDs would likely benefit from the addition of systemic immunosuppression, such as from DMARDs. Gastrointestinal (GI) discomfort is a frequent adverse effect of NSAID therapy, although frank GI bleeding appears to occur at a lower incidence than in adults. Scarring pseudoporphyria of sun-exposed skin is another risk associated with NSAID use. The long-term cardiovascular effects of NSAIDs in children have not been studied.

Glucocorticoids

Similar to many rheumatological diseases, JIA has been shown to respond to treatment with glucocorticoids (Chapter 86). Intraarticular glucocorticoid injections typically result in a near-immediate decrease in inflammation that is maintained for many months.[28] Accordingly, intraarticular injections may form the foundation of therapy for children with mild or limited oligoarthritis. In addition, intraarticular injections may be effective in children with more extensive arthritis and in those who are receiving concurrent systemic therapy. Randomized trials have shown unequivocally that injected triamcinolone hexacetonide has the longest duration of effect.[26]

JIA also may be effectively treated with systemic glucocorticoids. They are frequently used in the treatment of systemic features of JIA and may form the foundation of the treatment for the sJIA category, although biological therapies may significantly lessen the need for this practice.[26] The use of systemic glucocorticoids for the treatment of synovitis in children with JIA is not an uncommon practice. However, the risks, benefits, and appropriate use of this approach are less clear. The recent 2011 ACR Recommendations for JIA treatment do not include this use of systemic glucocorticoids because of the near-complete absence of any published evidence.[24] In general, most pediatric rheumatologists would agree that the use of DMARDs is preferable to the use of moderate-dose or high-dose systemic glucocorticoids for the treatment of synovitis in JIA. The anticipated adverse effects of long-term use of moderate doses of glucocorticoids includes growth failure, osteoporosis, cataract formation, glaucoma, hyperglycemia, hypertension, avascular necrosis of bone, striae, and others.[26]

Nonbiological DMARDs

The use of DMARDs was introduced in the 1980s (Chapter 87). The most widely used and studied is methotrexate, which has been shown in randomized clinical trials to be efficacious in treatment of JIA.[1] Following these studies, methotrexate became the cornerstone of therapy for many children with JIA. Methotrexate is typically administered weekly through either the oral or the subcutaneous route, although studies have shown subcutaneous methotrexate to be better absorbed and more effective.[1]

Methotrexate may be associated with several typically minor adverse effects, such as nausea and fatigue. Occasionally, methotrexate may cause liver toxicity, necessitating periodic measurement of serum aminotransferase levels for routine monitoring.

Leflunomide has been shown to be slightly less efficacious than methotrexate in the treatment of JIA.[1] It may serve as an alternative therapy for children who are intolerant of methotrexate. Sulfasalazine is used, to varying degrees, by pediatric rheumatologists and may be of particular benefit to children with JIA of the ERA category.[1] Hydroxychloroquine monotherapy has been demonstrated inefficacious in treating JIA.[1]

Biological DMARDs

The use of biological DMARDs for the treatment of JIA began in the late 1990s (Chapter 89). Etanercept, a TNF inhibitor, was the first studied and was shown to be efficacious in a randomized clinical trial.[1] Additional TNF inhibitors have been introduced and used in the treatment of JIA; adalimumab was also shown to be efficacious in a randomized clinical trial.[1] Notable differences have been discovered regarding the effectiveness of the TNF receptor fusion protein (etanercept) and the mAbs (adalimumab, infliximab, and others). mAb TNF inhibitors have been shown to be effective against two important JIA-associated conditions—anterior uveitis and IBD. Receptor fusion proteins have been shown to be far less effective in treating these conditions. The precise mechanism for these differences in treatment effectiveness is not clear but may be related to the ability of etanercept to bind lymphotoxin or the ability to bind surface membrane-bound TNF.[29]

Because the TNF inhibitors are large proteins, they must be administered parenterally, either by subcutaneous injection or intravenous infusion (see Table 53.2). TNF inhibitors are not generally associated with common medication adverse effects, such as headache or nausea, although they may result in injection site or infusion reactions. There appears to be a modest increase in the incidence of bacterial infections associated with TNF inhibitor use[30] and a significant risk of reactivation of latent tuberculosis.[29] Therefore individuals should be screened for tuberculosis infection prior to initiating treatment with TNF inhibitors.[24] The possible association between TNF inhibitors and an increased rate of malignancy in JIA remains an open question; however, currently, there is no convincing evidence of a strong increased risk of overall malignancy.[31]

In addition to TNF inhibitors, the T-cell costimulation modulator abatacept has been shown in a randomized clinical trial to be efficacious in the treatment of JIA.[1] Presumably, because of the effectiveness of TNF inhibitors, the use of abatacept has remained relatively limited in clinical practice.

The B-cell–depleting agent rituximab has been minimally studied in the treatment of JIA.[1] However, it appears effective in some instances, particularly in children who appear to have early-onset RA (teenagers with RF^+ and CCP-positive polyarthritis).

The IL-1 inhibitor anakinra has been shown in both uncontrolled and controlled studies to be particularly effective in the treatment of sJIA.[1,25] Similar to the experience in adults with RA, anakinra appears less effective in treating synovitis among children with the other categories of JIA. Additional IL-1 inhibitors (rilonacept, canakinumab) are also now commercially available and have been shown beneficial in clinical trials treating sJIA.[1]

Unlike other biological agents, the IL-6 inhibitor tocilizumab has been shown in randomized clinical trials to be efficacious in the treatment of both sJIA and polyarticular JIA.[1]

Treatment of Oligoarthritis (Arthritis of ≤4 Joints)

Because of fewer involved joints, oligoarthritis may generally be viewed as a milder form of JIA. However, significant disability can still occur, and children with this condition should not be assumed to have had good clinical outcomes without proper evaluation and therapy. The foundation of treatment for this JIA phenotype is intraarticular glucocorticoid injections. These injections may be administered in multiple joints concurrently and may be repeated, as needed.[28] A good response typically results in resolution of clinical signs and symptoms of arthritis for 4–12 months. DMARD therapy should be initiated in children who do not respond as desired to injections or who have more significant arthritis.[24] Methotrexate is typically the agent of first choice. Significant arthritis that does not respond adequately to methotrexate can be treated with TNF inhibitors.[24]

Treatment of Polyarthritis (Arthritis of ≥5 Joints)

Methotrexate is currently recommended for nearly all children with polyarthritis.[24] If a brief trial of methotrexate proves inadequate to control the arthritis, then TNF inhibitors are frequently recommended.[24] If an adequate response to the initial TNF inhibitor is not seen, then switching to another of the TNF inhibitors or switching to abatacept is currently recommended.[24] The most appropriate role of other effective biological DMARDs, such as tocilizumab (see Table 53.2), in the treatment of polyarticular JIA has yet to be clearly defined.

Treatment of Arthritis Involving Specific Joints

Arthritis involving the TMJ, hip, and sacroiliac joints may deserve special therapy. Destructive arthritis of the TMJ among children with JIA has been noted for decades. Clinical evaluation of this joint is particularly challenging, as symptoms are often absent initially, and physical examination findings may be normal. Accordingly, the optimal treatment for TMJ arthritis is unclear. Many authors recommend targeted therapy with intraarticular glucocorticoid injections, similar to the treatment of arthritis in other joints.[2] Increased systemic therapy is likely also appropriate, although TMJ arthritis has been known to demonstrate radiographic progression despite treatment with systemic TNF inhibitors and in the absence of signs of active synovitis of other joints.[2,22]

The presence of hip arthritis in JIA has been shown in several studies to portend a poor prognosis.[24] Accordingly, many authors advocate early intraarticular glucocorticoid injections and increased systemic therapy when active hip arthritis is identified.

Sacroiliac arthritis is strongly associated with the development of ankylosing spondylitis. Because axial arthritis has been shown to be less responsive to methotrexate therapy, current recommendations suggest a lower threshold for the initiation of TNF inhibitors when sacroiliac arthritis is present.[24] However, early treatment with TNF inhibitors, or perhaps even newer biological agents that inhibit IL-17 or IL-12/IL-23, may be optimal for the treatment of spondyloarthritis to help prevent progression of ankylosis in children.[27]

Treatment of Erosive Arthritis
